ABDOMINAL SUPPORTING BELTS

Pomeroy Belts are prescribed for conditions such as floating kidney, dropped stomach (or any form of ptosis), as well as post-operative, sacro-iliac, pre-natal, post-natal and obesity support

Our special models are the result of long experience in the making and fitting of surgical belts and are finished without superfluous straps, buckles and laces. If the patient desires a modish garment, Pomeroy fitters can incorporate the supporting element without detracting from its therapeutic effect.

Surgical Appliances Only

The POMEROY Frame Truss

SURGICAL APPLIANCES
for
OVER SIXTY-FIVE YEARS

Closely contacting the body at every point, the Pomeroy Frame Truss is unaffected by movement or changes in position. Combined with the water pad (first used by Pomeroy over sixty-five years ago), it is the one apparatus perfectly adapted to retain the hernia.

The fitting and shaping is done by experts since the usefulness of the Frame Truss depends on accurate adjustment. Guaranteed to retain hernia comfortably and securely when fitted by Pomeroy.

AROUND every turn of the road, amateur medical advice lies in wait for the young mother. Neighbors loving friends relatives who long to be helpful there are dozens of lay advisors whose counsels no physician could ever approve.

And—bad luck for babies—these advisors are happiest when they're holding forth on the all-important topic of infant feeding.

A baby's best defense against these well meaning meddlers is—his doctor's explicit formula. If that formula calls for evaporated milk, it's well worth while, for safety's sake, to specify the brand. You know that certain brands of evaporated milk measure up to your high standards, and that Borden's assuredly will do so. One word—"Borden's"—in your formula will make sure that your judgment, and not Mrs. Meddle's, prevails.

Borden's Evaporated Milk fulfills the strictest medical requirements for infant feeding. It is always wholesome, fresh and pure. Beginning with the selection of the raw milk, every step in its preparation is rigidly supervised under competent laboratory control.

May we send you a simple, compact infant feeding formulary and other strictly professional material which, we believe, you will also find interesting and valuable? Address The Borden Company, Dept. NE-44, 350 Madison Avenue, New York, N. Y.

Borden's Evaporated Milk was the first evaporated milk for infant feeding to be submitted to the American Medical Association Committee on Foods, and the first to receive the seal of acceptance. No formulas are given to the laity.

NUMBER 14

COMPLETE ABLATION OF THE THYROID GLAND IN A CASE OF CHRONIC LYMPHATIC LEUKEMIA WITH HYPERMETABOLISM*

BY WILLIAM DAMESHEK, M.D.,† DAVID D. BERLIN, M.D.,‡ AND HERRMAN L. BLUMGART, M.D.†

NUMEROUS investigators, in particular Minot and Means¹ and Friedgood², have commented on the striking resemblance which frequently exists between the symptoms of hyperthyroidism and those of chronic lymphadenosis (lymphatic leukemia). The symptoms of irritability, agitation, hyperactivity, asthenia, increased sweating, and loss in weight, associated with a warm, moist skin, a rapid pulse, and fine tremor of the hands are identical in both conditions. Whether these symptoms are dependent entirely upon the marked elevation in basal metabolic rate usually present in both diseases, or whether other more fundamental factors are operative is not certain. Krantz and Riddle³ stressed the importance of determining the basal metabolic rate as a guide to x-ray treatment in lymphatic leukemia, and pointed out that this test frequently gave a truer indication of the condition of the patient than the leukocyte count. They noted that the beneficial response which occurred following x-ray treatment was usually correlated with the resultant fall in metabolic rate.

The following case report deals with a patient who presented the typical features of chronic aleukemic lymphadenosis ("aleukemic lymphatic leukemia") and showed a basal metabolic rate of +65 per cent. It was thought that the symptoms she presented of extreme irritability, agitation, hyperactivity, asthenia, marked weight loss, drenching sweats, and palpitation might be directly dependent upon the elevated metabolic rate. When these symptoms became extreme, and the signs of beginning circulatory failure (edema of the legs, hydrothorax) developed, it was felt that complete thyroidectomy might offer the prospect of at least symptomatic improvement, especially since rest in bed, Lugol's solution and x-ray treatment of the lymph-nodes and spleen had proved of no value. This operative procedure, which has been found to be of definite value in reducing permanently the metabolic rate in over 60 cases of severe heart disease in this hospital, was accordingly done. The

striking effects which followed—in this first recorded complete thyroidectomy for leukemia—are the subject for the following case report.

REPORT OF CASE

Rose K., B. I. H., 18314 a 42 year old American Jewish housewife entered the Beth Israel Hospital on May 9, 1933, complaining of marked loss of weight. Her father had died at the age of 44 of carcinoma of the stomach. Two children were living and well, one child died in infancy from diphtheria. The patient had always been well except for attacks of 'bronchitis', which had occurred annually during the past three years. In 1926 she had weighed 130 lbs. In 1932, she weighed 125 lbs., but during the year before entry she had lost 12 lbs. Until the winter of 1932 she had considered herself well. At that time she suffered a severe attack of "grippe" associated with bronchitis. She recovered from this illness, but beginning in April 1933 she began to feel poorly although she had no specific complaints. In the latter part of the same month she noticed a large lump in her left groin and slight swelling of the left leg. She became increasingly nervous and lost weight, although her appetite remained good. She finally came to the out patient department of the hospital and was referred to the house medical service for study.

Physical examination on admission revealed a tall, thin garrulous hyperactive woman who appeared somewhat euphoric. The face was somewhat flushed, the skin warm and moist. The mucous membranes showed slight pallor. The edge of the liver was felt three fingersbreadth below the right costal margin extending well over toward the left of the midline. The spleen was greatly enlarged occupying the entire left upper quadrant of the abdomen. Its lower edge was felt below the level of the umbilicus and its upper edge could be percussed high up in the left axilla. The peripheral lymph nodes throughout the body were greatly enlarged. They were for the most part discrete, elastic, firm and non tender. The cervical nodes were very numerous and could be felt in the posterior and anterior cervical triangles and at the angles of both jaws. They were usually the size of large beans but several were walnut sized. The axillary nodes were very large especially in the left axilla where one of them was the size of a small orange. Conglomerate masses of nodes were present in both inguinal regions particularly on the left, where a large mass of about the size and shape of a pear was felt. This mass was very hard and firm and appeared to be adherent to the underlying structures. The epitrochlear nodes could not be felt. The left leg showed slight pitting edema. The rest of the examination, including that of the heart and lungs, was entirely normal.

The laboratory data on admission were as follows: the urine showed a "r.s.t." of albumin, the sediment being normal. Hemoglobin (Sahli) was 60.

From the Medical and Surgical Services and the Department of Pathology, Beth Israel Hospital, Boston and the Department of Medicine, Harvard Medical School, Boston.

†Dameshek, William—Associate Physician, Beth Israel Hospital. Berlin, David D.—Surgeon to Thyroid Clinic, Beth Israel Hospital. Blumgart, Herrman L.—Visiting Physician and Director of Medical Research, Beth Israel Hospital. For records and addresses of authors see This Week's Issue, page 772.

per cent, red blood cell count 438 millions, white blood cell count 9,000 per cu mm. Differential count of the white cells showed polymorphonuclear cells 34 per cent, lymphocytes 58 per cent, monocytes 7 per cent, eosinophiles 1 per cent. Most of the lymphocytes were of the immature or large type, and 12 per cent of the total white cell count was composed of lymphoblasts. The red blood cells showed slight hypochromia and slight change in size and shape, the blood platelets were normal. Blood non protein nitrogen was 35 mgs per 100 cc. Icterus index 6, blood cholesterol 153 mgs per 100 cc. The Wassermann, Kahn, and Hinton tests were negative. The basal metabolic rate fluctuated between +42 per cent and +61 per cent. An x ray of the lungs showed prominent, lobulated hilar nodes. X rays of the spleen were taken following the administration of 75 cc of a colloidal solution of thorium dioxide intravenously. The lower border of the spleen extended to within a few centimeters of the posterior crest of the ilium. The right lobe of the liver appeared to be increased in size and slightly low in position.

FIGURE 1 Chart illustrating the effect upon the basal metabolic rate and the body weight of compound solution of iodine x ray treatment and total ablation of the thyroid gland

The clinical diagnosis of chronic lymphatic leukemia (aleukemic) was made on the basis of the symptoms of weakness and loss of weight, the physical signs of generalized lymphadenopathy and splenomegaly, and the definitely abnormal blood picture which showed an absolute increase in the number of lymphocytes with the appearance of many immature lymphocytes and lymphoblasts. The hypermetabolism was considered to be associated with the leukemic process.

A sternal bone marrow biopsy was done. This was essentially negative and showed but little infiltration with cells of the lymphoid series. The ratio of nucleated red blood cells to white blood cells was 0.5 to 1 (normal about 1 to 1). Differential count of the bone-marrow white blood cells showed the following: mature polymorphonuclears 35 per cent, metamyelocytes 64.5 per cent, myelocytes 24.5 per cent, myeloblasts 10 per cent, histiocytes 15 per cent, and lymphocytes 5.0 per cent.

Biopsy of one of the axillary lymph nodes on microscopic examination by Dr. Monroe J. Schlesinger showed the node to be largely run over and replaced by a single type of cell. Although the sites of many of the lymphoid follicles can still be made out by the arrangement of the stroma the cells in these areas do not show the orderly arrangement of germinal centres surrounded by

lymphoid cells. Instead the whole area is a solid mass of the same type of cells found throughout the node. These replacing cells also stuff the peripheral and other sinuses and are found infiltrating the capsule. This capsular infiltration is continuous with the underlying infiltration. The infiltrating cells have large, pale, vesicular, irregularly shaped nuclei with a sharply cut nuclear membrane, and often one or more definite nucleoli. The cytoplasm of these cells is less obvious, but consists of a narrow, irregular rim, which is slightly basophilic and has no definite cell membrane. Mitotic figures are found throughout and also a rare cell with a multilobed large nucleus resembling a giant cell nucleus. There is no definite increase in fibrous tissue and no areas of necrosis. Diagnosis: malignant lymphoblastoma, possibly lymphatic leukemia.*

The patient remained in the hospital on her first admission from May 9 to May 23, 1933. Her temperature ranged between 98 and 99.5° F, her pulse between 80 and 100 per minute. She weighed 113 lbs on admission, 112.5 lbs on discharge. On May 18, the administration of compound solution of iodine was begun in a dosage of 10 minims three times daily. This was continued throughout the remainder of the patient's stay and for a month following discharge. The patient was discharged to a convalescent home, where she remained for a month. There had been no change in her condition while she was in the hospital.

She returned to the Blood Clinic on June 23, 1933. She was still extremely hyperactive and complained of extremely distressing sweats usually nocturnal, and drenching in type. There had been some slight gain in weight, but the metabolic rate was still markedly elevated (+63 per cent) despite the continued administration of Lugol's solution. On July 14 the cause of her continued gain in weight to 123 lbs despite the tachycardia (120 per minute) and the hypermetabolism was found in marked pitting edema of both legs. It was felt at this point that the chief symptoms in this case were due to the markedly elevated metabolic rate leukemic in origin, to be sure, but bringing about, none the less an actual "burning up" or dissipation of the patient's energies and possibly causing some degree of cardiac decompensation. The possible presence of a hyperplastic thyroid gland was also considered. The possibility of alleviating these symptoms and thus preventing future damage to the myocardium by complete ablation of the thyroid gland suggested itself. After considerable discussion it was decided that x-radiation over the lymph nodes and spleen should first be instituted. If this proved unsuccessful in alleviating the patient's hypermetabolism and her associated symptoms, thyroidectomy might then be done. She was accordingly given a series of deep x-ray treatments in the X-ray Department under the supervision of Dr. Harry F. Friedman. Six ten minute treatments over the spleen (80-100 roentgen units) were given and followed by three ten minute treatments over the anterior chest of 100 roentgen units. These treatments were given on successive days beginning July 17 and concluding July 28.

On July 21 her weight was 112 lbs, a loss of 11 lbs in one week and examination disclosed almost complete absence of edema of the legs. On July 28 she weighed 104.5 lbs and the basal metabolic rate was +65 per cent. She seemed a little better on August 11 but her pulse was still 120 per minute, and the lymph nodes, spleen and liver showed no

*It may be noted that Dr. Schlesinger includes under the diagnosis of "malignant lymphoblastoma" both lymphosarcoma and lymphatic leukemia. He maintains that by microscopic section alone without knowledge of the blood it is impossible to distinguish from examination of a single lymph node between lymphatic leukemia and lymphosarcoma.

essential change from previous examinations. Blood studies showed very little change except for slight leukopenia (5000 per cu mm). In September, she felt and looked very badly, was extremely nervous, irritable, hyperactive, and was again showing edema of the legs. She was finally readmitted to the House on September 8, 1933.

active, and rapid and a soft, blowing systolic murmur could be heard over the entire precordia. Generalized lymphadenopathy was present as described in previous examinations. No diminution in size had occurred. If anything most of the nodes were large. There was pitting edema of both legs, especially marked in the left. Blood pressure was 120

FIGURE 2. Photomicrograph of section of lymph node removed at biopsy. $\times 900$. Note the effacement of the normal architecture of the node with extensive proliferation of primitive lymphocytes typical of lymphadenosis (lymphatic leukemia).

Examination at this second admission showed a markedly emaciated hyperactive woman moving about very restlessly in bed. The skin was very warm and moist. There was no exophthalmos nor lid lag. The thyroid gland was not palpable. There was dullness and diminished tactile and vocal fremitus at the bases of both lungs probably due to fluid. The heart sounds were very loud hyper

systolic, 65 diastolic mm Hg. An x-ray of the chest disclosed an area of dullness and obliteration of the costophrenic angle at the right base interpreted as lesion at the right lower lobe with probably a small amount of fluid, of leukemic infiltration. X-rays of the abdomen showed that the liver and spleen were larger than on previous examinations. The urine was normal except for many leukocytes.

on one occasion. An electrocardiogram was normal except for slight right axis deviation. The blood at this time showed a definite though slight anemia together with a leukopenia. The hemoglobin ranged between 55 and 60 per cent, the red blood cell count between 3.04 and 3.80 millions, and the white blood cell count between 2400 and 5200 per cu mm. The basal metabolic rate was still strikingly elevated ranging between +48 and +56 per cent, and the blood cholesterol content was correspondingly low 101.112 mgs per 100 cc. Again, no drop in metabolic rate followed the administration of Lugol's solution.

On September 26, 1933, total ablation of the thyroid gland under gasoxygen anesthesia was per-

metabolic rate was +16 per cent. On October 20, she weighed 109 lbs, and her pulse was 80 per minute. Although she was still quite nervous and excitable, she seemed much quieter. She said she felt stronger and was pleased at the complete loss of palpitation, which had been so annoying before operation. She continued to have profuse night sweats. On examination, she was definitely less agitated, and the lymph nodes seemed perceptibly smaller. Basal metabolic rate was +19 per cent.

For the next month, until November 17, the clinical course was irregular. There was no further gain in weight, in fact there was a slight loss—and there was no further drop in basal metabolic rate (+23

FIGURE 3 Photomicrograph of section of thyroid gland removed at operation. $\times 118$ Note the normal structure of the thyroid acini

formed by Dr. Berlin. The same technique was used as described in previous papers on total thyroidectomy in severe cardiac disease.^{1,2} The postoperative course proved essentially uneventful.

The complete thyroid gland at removal weighed 145 Gm. We are again indebted to Dr. Schlesinger for the following description of the gross and microscopic appearance of the gland: "The outer surface had a grayish pink to purple appearance. Microscopic examination revealed thyroid tissue in which the acini are uniform in size, shape, and distribution. They are lined by a flattened layer of cuboidal epithelium, and the lumina are filled with uniformly staining colloid material. There is no particularly noticeable infiltration of lymphocytic or other types of cells, and there is no evidence of hyperplasia."

Eleven days after operation (October 7) the basal

metabolic rate was +16 per cent on November 2). However, on November 17, she presented herself at the Blood Clinic and maintained she felt "wonderfully well." She was much quieter, and her sweats had entirely ceased. She had gained 4 lbs since the preceding week, and the metabolic rate showed a marked drop to -6 per cent. The lymph nodes of the neck were barely palpable, and the axillary and inguinal nodes had diminished about 50 per cent in size. The spleen was felt three fingersbreadth below the left costal margin and appeared to be about one-half of its previous size.

From that time until the present, there has been continued and striking improvement. Gain in weight continued at the rate of 3.5 lbs per week. The metabolic rate fell to -13 per cent on December 1 and to -22 per cent on January 12, at which time small doses of thyroid extract were administered.

The blood cholesterol has risen from its pre-operative low of about 100 to its present value of about 290 mgs per 100 cc. There is no further sweating, the patient usually feels somewhat cold and her skin has become rather dry and coarse. The symptoms of full blown myxedema developed about three months after operation when the metabolic rate fell to -22 per cent.

The most striking findings, however, are those referable to the lymph nodes, spleen, and liver. At the present writing the cervical and axillary lymph nodes have completely disappeared and the large

the metabolic rate reached a level of -6 per cent. Palpitation of the heart ceased earlier. The last and most distressing symptom to leave was the severe drenching night-sweat. Despite the development of clinical myxedema at a metabolic level of -22 per cent, the patient said she felt better than she had for years.

2 Signs

The signs referable to the circulation were the first to become modified. Blumgart⁶ has demonstrated the interdependence of the velocity of blood flow with the basal metabolic rate, and upon this basis rests the concept of the amelioration of the symptoms of cardiac failure by thyroidectomy.^{4 (a) (b) 7} The pulse in our case, averaging 120 per minute before operation, rapidly diminished as did the fluid in the right pleural cavity.

The warm moist skin gradually became dry and somewhat coarse. The patient herself changed from an agitated and incoherent person to a softly-spoken, apparently calm individual. The peripheral lymph-nodes gradually became smaller in size until finally even the hard masses of inguinal nodes became difficult

FIGURE 4 Roentgenogram of abdomen September 11, 1933. Colloidal solution of thorium dioxide had been given in May 1933 and the spleen and liver continued to show the presence of "thorotrast." Note the extremely large size of both the liver and spleen; the latter organ extending almost to the pelvic brim.

masses of inguinal nodes have diminished about 90-100 per cent in size. Simultaneously, the spleen has become strikingly diminished in size and can now be felt just below the left costal margin. This is well brought out in the x-rays of the abdomen.

The blood findings during this period (September 26, 1933; January 12, 1934) have shown slight though progressive improvement. There has been gradual amelioration of the anemia, although neither iron nor liver was given, and the leukocyte count has slowly but steadily risen. The differential count has shown a gradual approach to a more normal formula, and the lymphoblasts have entirely disappeared.

COMMENT

A. Results

The results which followed complete removal of the thyroid gland in this case of chronic aleukemic lymphadenosis with hypermetabolism are analyzed below.

1 Symptoms

The extreme agitation, hyperirritability, over-excitement, and insomnia all disappeared when

FIGURE 5 Roentgenogram of abdomen December 15, 1933. Note that the spleen has been reduced markedly in size, extending only a short distance below the left costal margin. The liver also has been definitely reduced in size.

to feel. The spleen, which had occupied almost the entire left half of the abdomen, rapidly became smaller when the metabolic rate reached -6 per cent, and within six weeks had regressed so that it could be felt just below the left costal margin. A myxedematous facies was finally noted about three months after operation, at which time the metabolic rate was -22 per cent and the patient had gained about 25 lbs in weight.

3 Basal Metabolism

The basal metabolic rate before operation fluctuated between +42 per cent and +65 per cent (figure 1). Slight diminution in rate occurred during the patient's first admission to the hospital following several days' rest in bed. Lugol's solution was given in dosage of ten minims three times daily for a period of three weeks during and following her first admission, and for two weeks during her second admission. No diminution in rate occurred on either of these occasions, in fact, the metabolism appeared to increase definitely during the first period of treatment with Lugol's solution. This is contrary to the experience of Friedgood.²

X-ray treatments given almost daily for eleven days in a total dosage of 880 roentgen units over the spleen, lymph-nodes and mediastinum caused no diminution in metabolic rate. It is, to be sure, possible that diminution in rate might have occurred with further x-radiation, it was felt, however, that the patient's progressively downhill course militated against continued therapy.

Striking drop in metabolic rate to +16 per cent occurred eleven days after operation. For about two months, there was no further change, at which time a sharp drop to -6 per cent and -13 per cent took place. Another two months passed without further change, when a further drop to -22 per cent was noted. At this time, the patient presented all the clinical features of myxedema, and it was decided to give small doses of thyroid.

4 Blood Cholesterol

The cholesterol content of the blood in this case varied inversely with the basal metabolic rate. With the highest metabolic readings, values of 100-112 mgs per 100 cc were obtained. Following thyroidectomy, gradual rise took place, so that two and a half months after operation, when the basal metabolic rate was -13 per cent, the blood cholesterol was 292 mgs per 100 cc. These findings conform to the observations of Hurxthal³ who showed that the blood cholesterol content is low with hyperthyroidism and high in myxedema.

5 Blood Cells

The cellular constituents of the blood are presented in table 1. When the patient first presented herself at the hospital there was slight hypochromic anemia together with normal leukocyte and platelet counts. Differential count of the white blood cells disclosed a marked increase in the absolute number of lymphocytes and monocytes with the appearance of many lymphoblasts and histiocytes. As the patient's illness increased in severity the anemia increased and became normocytic and the leukocytes and blood platelets became much diminished. Lymphoblasts were consistently present. Following operation, there was gradual rise in red cell count (without iron or liver therapy) to 4.90 millions together with rise in leukocytes to about 6000 per cu mm and rise in the number of blood platelets. The lymphoblasts disappeared completely two and a half months after operation, although there was a continued lymphocytosis with the presence of many large lymphocytes. At this time, coincidental with the rapid regression in size of the lymph-nodes and spleen several lymphocytes showing extreme vacuolization of the cytoplasm were seen. It was thought that they might represent lymphocytes which had become deteriorated in the nodes and had appeared in the peripheral blood. Krantz and Riddle³ noted that "there was a definite tendency for the large lymphocytes and immature lymphocytic cells to increase as the heat production rose" and to diminish with diminution in metabolic rate.

B Theoretical Implications

It is not our purpose in this preliminary report of a single case to enter into any extensive discussion regarding the numerous theoretical speculations which are of interest. Minot and Means¹ and Friedgood² have adequately discussed the often striking resemblances between hyperthyroidism and chronic lymphatic leukemia. Friedgood² feels that the elevated basal metabolic rate of both diseases is intimately related to the sympathetic nervous system. Most investigators however conclude that the increased heat production in hyperthyroidism is due to the action of an excess amount of active principle liberated by a hyperplastic thyroid gland and that the hypermetabolism of leukemia is due to the increased metabolic activities of proliferating white blood cells. This question is not settled by the results which followed thyroidectomy in our case.

The regression in size of the lymph-nodes and spleen which followed thyroidectomy may have been spontaneous although it was felt that this possibility was unlikely since such extreme regression had never before been noted in our experience. It might have been the result of

x-radiation although this is rendered unlikely because diminution in size did not occur for almost five months following this form of therapy. That it was due to the injection of thiothorast is also unlikely because other investigators, principally Zadek¹⁰, have reported on the inefficacy of this form of treatment in chronic lymphatic leukemia. The possibility was considered that the diminution in size and presumably in the degree of proliferation of lymphoid tissue was the direct result either of the fall in basal metabolism or of the lack of the growth-promoting influence of the thyroid secretion.

Answers to these questions may appear when more cases are studied. In this paper it is our object to present the results which followed thyroidectomy in a case of chronic lymphatic leukemia with hypermetabolism in the hope that others may be prompted to utilize the same procedure in similar cases and record their observations.

SUMMARY

A woman aged 42 with the signs of chronic aleukemic lymphadenosis ("aleukemic lymphatic leukemia") presented a basal metabolic rate of +65 per cent. It was thought that the continued loss in weight, profuse drenching sweats increasing nervous symptoms and beginning circulatory failure might be due to the markedly elevated metabolic rate. When the patient became extremely ill and failed to respond to rest in bed, Lugol's solution and x-ray therapy, complete ablation of the thyroid gland was performed. Following this procedure the metabolic rate dropped strikingly, the clinical signs and symptoms of hypermetabolism disappeared as did the signs of circulatory failure, the patient gained weight, and the lymph-nodes and spleen regressed about 90 per cent from their original size. There was complete disappearance of all the patient's symptoms and the blood-picture became almost normal. Improvement has continued for five months after thyroidectomy was performed.

Remissions have been frequently reported in this disease and it seems conceivable that the events reported here are merely the expression of such remissions but the rapid onset of improvement after the treatment leads us to believe that the operation was at least partly responsible for the improvement.

We emphatically do not recommend this form of treatment for other types of malignant disease.

PRESIDENT ELIOT'S RELATIONS TO MEDICINE*

BY WALTER B. CANNON, M.D.†

AT the Harvard University Commencement in 1909 an event occurred which was quite unprecedented. Two honorary degrees were given to one man. I remember vividly the sharp reaction of incredulous surprise which flashed over Mr. Eliot when, after President Lowell had conferred upon him the Harvard degree of Doctor of Laws, he again called his name and proceeded to bestow also the degree of Doctor of Medicine. In characterizing Mr. Eliot's services to medicine President Lowell symbolized the reforms which his predecessor had accomplished, by the expression, "Not in its buildings alone, but also in the instruction and research within its walls, he found the Harvard Medical School brick and left it marble." Through improvements which he made in our Medical School, however, President Eliot had a wide influence on medical instruction throughout the United States. It is proper, therefore, that we should recognize on this day of remembrance not only his local achievements but also the widely extensive influence of his policies and activities. In bringing before you his outstanding relations to our profession—his contributions to reform in medical teaching, to the advancement of dentistry, to the support of preventive medicine and public health, to the extension of western medicine into oriental countries, and to the freedom of medical research—I shall rely largely on his official reports and on speeches in which he advocated his views.

I

In order to appreciate the significance of President Eliot's vigorous and effective efforts at reform in medical education, we must understand as clearly as possible the status of affairs both in the world at large and in the medical

schools of this country, at the time of his entrance into the Presidency of Harvard University in 1869.

Two decades of the latter half of the 19th century had already nearly ended. That marvelous half-century, according to Osler, witnessed an application of the experimental study of physiology and pathology which did more to emancipate medical practice from the routine and thralldom of authority than all the work of all the physicians from the days of Hippocrates to those of Jenner—a period of nearly 2300 years. Just before those five decades of stupendous change had begun, ether had been proved a reliable anesthetic—a forward step which became, perhaps, quite as important for experimental medicine as it was for practical surgery. And although there had been other important steps forward in medical science before the discovery of general anesthesia, the stirrings and quickenings of the great advance began shortly thereafter. Claude Bernard, at Paris, and Carl Ludwig, at Leipzig, continued their brilliant discoveries in physiology, Bernard revealing the secrets of digestion and the nice control of the circulating blood by nerves, and Ludwig ingeniously inventing new methods, suggesting new ideas of bodily function, and stimulating scores of young men, who resorted to him from various countries, to undertake careers in medical research. Through his treatise on "Cellular Pathology," Virchow, in 1858, suddenly revealed an instructive way of regarding the processes of disease. A year later Darwin published "The Origin of Species," a book which had a most disruptive and fertilizing effect on biological thought and investigation. In 1865 Pasteur, by his examination of the causes of widespread death in silkworms, commenced the researches which illuminated the whole realm of infectious disorders and gradually brought about fundamental transformations in medical and surgical procedures. The first application

*A Memorial Address given at the Harvard Medical School on the Hundredth Anniversary of President Eliot's Birth.

†Cannon, Walter B.—George Higginson Professor of Physiology Harvard University Medical School. For record and address of author see "This Week's Issue" page 772.

of Pasteur's ideas was known in 1867 when Lister published his classic record of two years' study on the avoidance of pus in wounds by applying what he called the "antiseptic principle." Meanwhile, investigations on metabolism had been undertaken by Voit and Pettenkofer, Villemin demonstrated that tuberculosis was transmissible, and Cohnheim was expounding his revolutionary observations on the inflammatory process. In short, the era of experimental medicine had been well begun, with its marvelous efflorescence of discoveries of the functions of organs and systems of organs, of the nature and causes of disease, and of rational modes of treatment. As time passed these fruitful efforts became organized in the sciences of experimental physiology and pathology, in biological chemistry, in bacteriology and immunology, and in the bedside applications of scientific methods to the practical problems of medicine and surgery.

In the presence of these stupendously important developments in certain European centers, what was the attitude of the teachers of medicine in the United States? So far as preparing students to become intelligent future practitioners of medicine was concerned, rendering them capable of understanding and appreciating the progressive spirit of their profession, it is clear that the teachers were as blind to the significance of events as if they had been living in the Dark Ages. The conditions which prevailed in the Harvard Medical School may be regarded as typical of and perhaps superior to the conditions generally found throughout the country. In his Annual Report of 1870-71 President Eliot described the mode of teaching which had prevailed previous to his administration. Let me quote his description,—

'The main strength of the body of teachers in an American medical school is spent upon long courses of lectures on the chief medical subjects which are given every year during from four to five months of the autumn and winter. At large medical schools these lectures are so numerous that the student who attends them all goes to five or six a day and of course remembers very little about any of them. The same lectures are repeated every year. The student who spends two winters in the same school pays twice for the same lectures. If he remain a third year he can attend them gratuitously. A candidate for the degree of Doctor of Medicine has been required to prove that he has attended somewhere two such terms of lectures, and one of these two in the institution at which he is seeking his degree. At the best schools a formal examination of candidates for the degree has been held but this examination has been private hasty and notoriously lax. A majority vote of the body of examiners admits the candidate to the degree so that the new doctor may be and frequently is utterly ignorant of nearly half the subjects of examination. It has been the pecuniary interest of the teachers composing a medical faculty to have as many pupils as possible and to grant as many degrees as possible their receipts being proportionate to the number of fees paid for attendance at lectures and for graduation. Finally the students to whom

this deplorable system of instruction has been applied, are, in the great majority of cases, persons of scanty preliminary training. Very few are graduates of colleges and very many are deficient in the elementary branches of what is called an English education. No medical school in the country would venture to publish uncorrected, one quarter of the theses which candidates for a degree present as one evidence of their attainments.

'It seems almost incredible that the grossly inadequate training above described should be the recognized preparation of aspirants to a profession which was once called learned, and which preeminently demands a mind well stored and a judgment well trained—a profession in which ignorance is criminality and skill a benefaction—a profession which penetrates the most sacred retreats of human love, joy, and sorrow, and deals daily with the issues of life and death.'

Such was the devastating criticism of medical education of that day which the new President outlined to the alumni of the University. The "notoriously lax" examination which he mentioned was conducted in the following manner. Nine professors representing nine different important subjects sat each at a table in the examination room. Nine students were admitted to the room in a group, and each sat down with a professor. At the end of ten minutes a bell rang and each student moved along to the next table. This process continued until at the end of ninety minutes all had been examined, whereupon they filed out. Each professor had a card, white on one side and marked with a black spot on the other. In order to secure the individual professional judgments, uninfluenced by conference, the Dean immediately called out separately the names of the students in the group, and after each name the professors simultaneously held up their cards,—the white side meaning approval the black spot disapproval. If five professors displayed the white side of the card, that is if the student was recognized as having passed five of the nine subjects on which he had been examined, he was granted the degree of Doctor of Medicine. Thus, at that time a young man could go forth from this School quite ignorant of four of the nine branches of medicine which he was supposed to use in his practice. I have heard from the lips of William James, who received his medical degree here in 1869, an account of his examination under this system. When he sat at the table with Oliver Wendell Holmes he was asked to describe the circle of Willis. James briefly mentioned its position and relations, whereupon Holmes remarked, "If you know that you know everything. Now, tell me all about the folks."

It is clear that an education of the character just described was not even remotely calculated to give insight into the revolution in medical science and practice that was already well along in its progress. Such an education had no gleam of true scholarship in any of its features. It

was utterly lacking in the close personal contacts of student with patient which are essential for training in effective practice. In the main it was neglectful of the methods and results of sound investigation, and oblivious of everything except the limited outlook of shortsighted teachers. It provided, therefore, instruction which resulted in supreme self-satisfaction and complacency,—an attitude negligent of, if not hostile to, new and important developments. An emphasis which was placed on a spurious "practicality" long prevented the adoption of modes of treatment, such as Listerism, for example which had proved elsewhere to be of the utmost practical benefit. In so far as the educational routine was not absurd it was perilously negligent of values of human life.

Obviously the stage was set for a reformer—one with strong convictions and great courage—and that, fortunately for the Harvard Medical School, was what President Eliot proved to be. In 1869, quite unheralded and for the first time in the history of the University, he broke the tradition of being only a nominal head of the School, and took his rightful place as presiding officer at the meetings of the Medical Faculty. Almost immediately his influence was felt, and when at one of the early sessions the dominant member of the faculty at the time, Dr Henry J Bigelow, asked why in a few months so many changes were proposed, whereas for eighty years the School had been running along smoothly and prosperously, the answer came—after a moment of dead silence—in the firm softness of President Eliot's voice, "I can tell Dr Bigelow the reason. There is a new President."

The establishment of respectable standards was argued against as being not only detrimental to the popularity of the School and therefore likely to affect unfavorably the professors' incomes, but as being vaguely detrimental to the chances of discovering the "born" physician and surgeon who might not be revealed unless the classes were large. Dr Bigelow declared that the young President was going to wreck the Harvard Medical School, it would soon cease to exist if his revolutionary plans were approved. "He actually proposes," said Dr Bigelow, "to have written examinations for the degree of Doctor of Medicine. I had to tell him that he knew nothing about the quality of the Harvard medical students, more than half of them can barely write. Of course, they can't pass written examinations." On his part, the "young President" did not flinch, nor did he mince his words. In his report for 1869-70, he wrote

The whole system of medical education in this country needs thorough reformation. The course of professional instruction should be a progressive one covering three years and the student

should give his attendance at lectures and recitations, at hospitals and laboratories, during the whole year. The Medical Faculty have been actively discussing these much needed changes, and will shortly rearrange their programme of instruction."

President Eliot's confidence that the new program would be adopted was doubtless based largely on his own sense of the righteousness of his cause and the power of his argument, but it rested also on the support which he received from a few members of the faculty who were convinced that reform was essential. Among these supporters were the Dean, Calvin Ellis, Dr James C White, Dr David W Cheever and, after he freed himself from the pressure of Dr Bigelow's thumb, as he explained, Dr Oliver Wendell Holmes. Even though the President was able to persuade the majority of the Medical Faculty and the Corporation to vote for the new regime, he still had to convince the Board of Overseers of the importance of the reforms, and so far as possible Dr Bigelow had been using his powerful influence to defeat the President's efforts in that body. There was doubt of the outcome. At a critical moment Mr Charles Francis Adams, ex-Minister to England and then Chairman of the Board, called another member to the chair, without intimating on which side of the controversy he was about to speak. Very simply, but with deep feeling, he told of a young graduate of our Medical School who had settled near his home in Quincy and whose attendance on workmen there had resulted in three mysterious deaths. After questions by an older practitioner the fact came out that the young man had, through ignorance, given fatal overdoses of morphine—a result of receiving his medical degree after passing only a majority of the subjects in which he had been examined. Mr Adams urged that it was high time that the proposed reforms were approved, and his pointed story carried the day.

Financially the new move was hazardous. The income of the School had depended wholly upon fees from students, and the raising of the time requirements for medical instruction to three years and the lengthening of each year from four months to the full academic period necessarily reduced the attendance. Repeatedly during the decade that followed there were appeals in the Annual Reports for financial aid. In 1871-72 President Eliot urged strongly the need for endowment.

"It would be difficult," he affirmed, "to overstate the importance of the effort which this single School is making, with no support except the approval of the profession, to improve the system of medical instruction in the United States. The ignorance and general incompetency of the average graduate of American Medical Schools at the time when he receives the degree which turns him loose upon the community, is something horrible to contemplate considering the nature of a physician's functions and responsibilities. The early mistakes of a young lawyer or a young minister are no great matter, not

much is staked upon his skill and wisdom and the community does not suffer irremediable losses and multiplied miseries if novices in these professions are left by the Schools in such a condition that they have to learn some pretty elementary lessons by practice. In the medical profession it is far otherwise. The mistakes of an ignorant or stupid young physician or surgeon mean poisoning maiming and killing or at the best they mean failure to save life and health which might have been saved, and to prevent suffering which might have been prevented. The effect upon the community of allowing the great mass of young physicians to learn the rudiments of their art by practicing it, can only be compared to the effect upon an army in the field of offering it with men who have to learn the elements of the art of war by practice in the face of the enemy. This comparison does not exaggerate the evils of the prevailing system of medical instruction in this country. The Harvard Medical School has successfully begun a revolution in this system. A liberal endowment of the School would insure the complete success of the undertaking and would encourage other schools to imitate the good example. There is no department of the University upon which money can be more worthily or more usefully bestowed none in which endowment funds would have more immediate or more lasting effects to advance learning and to relieve the sufferings and promote the happiness of mankind.

The financial troubles of the School were not rapidly resolved for about ten years later in his Report of 1880-81, the President was still urging the importance of generous support for medical education and research.

So long as medical schools he declared 'are conducted as private ventures for the benefit of a few physicians and surgeons who have united to form a corporation or a faculty the community ought not to endow them for it is contrary to the best interests of the public that medical education should be conducted in that way. The experience of the past hundred years in this country proves that such medical schools will not be endowed. The objects of endowment in medical education are precisely the same as in other departments of education namely to provide permanent means of securing the most competent persons for its professorial chairs of helping poor students of rare capacity, and of advancing knowledge by new researches. It is the primary object of medical science and art to defend and improve the life that now is—the life of the individual of the family and of society but since it is impossible to separate physical from mental and moral well being the domain of medical science is really co-extensive with human nature. Whatever motives influence benevolent persons to endow institutions which teach the humanities or theology should also avail for the endowment of medical education. The seed and the fruit, the planning and the harvesting may be different in kind but these various cultures all have in view a common end namely the improvement of man's highest state.

He once remarked "The first step towards obtaining an endowment is to deserve one." And in this same Report (1880-81) he was able to point with some pride to the fact that since 1871, when the Harvard Medical School ceased to be a private venture and became a constituent department of the University it had received by gift and bequests \$270,000.

President Eliot not only had great satisfaction in observing that the number of students gradually increased in spite of high standards, but was cheered by the adoption of the reforms made prominent at Harvard by other schools in the country. It is true that a graded course had been started earlier in the Chicago Medical School but the requirement was not strictly adhered to and the example was without noteworthy influence on the generally prevailing low standards. "The first real reform in American medical education" Garrison declares in his "History of Medicine" "was made in 1871 by President Charles W. Eliot of Harvard who raised the entrance requirements of the Harvard Medical School lengthened its curriculum to three years and graded it providing at the same time better facilities for clinical and laboratory instructions." The changes soon brought about an improvement of the quality of the students who entered on the study of medicine. In his Report for 1876-77 the President rejoiced in the possession of literary or scientific degrees by 44 per cent of the students an increase of nearly 90 per cent during the first seven years of his administration. And he rejoiced also that the University of Pennsylvania and the University of Michigan had to some extent followed the advances started at Harvard. He predicted that these actions meant the "speedy downfall of the old system of medical education." With extraordinary exactness he foresaw events.

"The schools connected with universities will abandon it (the old system) first" he prophesied "and the schools which are commercial ventures will do likewise when public opinion has so made itself felt on this subject that it will discredit a physician or surgeon to be connected with a school which admits to the profession rude ignorant and unskilful men." It was not until thirty-five or forty years later, however that this prediction came true when by abolition of the low-grade medical schools of the country, the number of schools was reduced from approximately 150 to approximately 85 because of the pressure of public and professional condemnation.

One receives a lasting impression of the continuity of a great institution such as Harvard University and the patience and persistence required of leaders who are eager to introduce improvements in its structure and customs by reading a series of the annual reports. Long before a change is adopted the suggestion of the change is clearly advocated and is as a rule repeatedly urged. In his Report for 1879-80 President Eliot outlined a plan for an elective fourth year in the medical curriculum, a year which would allow a better distribution of studies and a greater thoroughness of instruction—indeed instruction in small sections such that the student might have intimate contact with

patients The usual mode of teaching at the time was by means of clinical "exhibitions in large rooms appropriately called theaters" and "clinical visits in large groups" As the President described the method,

"The patient sits on a revolving table, and turning slowly around in the focus of a large amphitheater containing 300 or 400 students, supplies, it may be, an interesting illustration for a lecture, but affords the students only a very imperfect practice in that acute and accurate observation upon which the correct diagnosis of disease depends If it be said that it is impossible to give such personal instruction in a large school without a great number of clinical instructors, the answer is two-fold first, that the number of clinical instructors ought to be as large as the community can well supply and, secondly, that the University should be more concerned to have a very good school of medicine than a very large one"

These views resulted ultimately in the extension of the medical course by a required fourth year, and a long time later in the teaching of all students in small groups, and at a still later date in the development of clinical clerkships and the assumption of responsibilities for examining patients by the students themselves

Another illustration of the slow course of events is found in President Eliot's early reference to the limitations placed upon the Medical School because of the necessity of appointing as members of its clinical faculty men having positions in the Boston hospitals When a vacancy occurs in some clinical department, he wrote in his Report for 1888-89, "the question before the Governing Boards of the University is—not who is the best man for the place in Boston or elsewhere—but who is the most available man as a teacher among the Boston practitioners already holding cognate hospital appointments given by other Boards of Trustees, who in making their selection had teaching not at all in mind More than once this limitation of choice has proved unfortunate More than once the School and the community have lost an important medical reinforcement because the School was not in a position to offer to the desired person an adequate hospital appointment as well as a professorship"

Again we note a proposed reform which required many years for its actual achievement The criticism offered in 1888-89 was repeated frequently thereafter in comment and conversation Not until 1912, however, when Harvey Cushing was called to the Brigham Hospital from Johns Hopkins, and David L. Edsall of Washington University, St. Louis, was appointed in Medicine at the Massachusetts General Hospital, was the tradition broken and a practice begun which allowed the Medical School to offer clinical positions to the best men wherever they might be found in any part of the world

II

We turn now to a brief consideration of President Eliot's attitude toward those disorders of

the body which are the concern of the dentist He watched with care the developments of our Dental School, which had been established only a short time before the beginning of his administration Again his local interest had extensive effects In an address which he made in 1878, he took occasion to offer some rather strong advice to the members of the American Academy of Dental Science In doing so, he raised the question as to whether certain signs of anxiety among them, regarding the improvement of dental education and the raising of professional standards, should not be used to avert certain evils He pointed out that among such evils was the admission to the profession of thousands of "ignorant men attracted by its apparent profitableness, and debarred by no law, no established usage, and by no intelligent discrimination of the public against uneducated practitioners" Furthermore, he declared that it was not a favorable sign that the best literature on dentistry was to be found outside the United States, indeed, that only foreign dental literature showed any indication of scientific enthusiasm or disinterested devotion to study or to teaching He insisted that the dental schools throughout the country received only a small proportion of the men who entered the profession, and they set before their students standards of attainment which were much too low It is easy to recognize in this vigorous and straightforward attack on low standards of dental education a resemblance to the attitude which the President took when he faced the Harvard Medical Faculty in 1869 Indeed, he himself called attention to the precedents which the medical profession offered

"So young a profession as dentistry may well look, in searching for means of exalting the calling, to the experience of the elder profession of medicine. It cannot fail to be observed that one of the things which makes the profession of medicine a liberal profession is the zeal for scientific research which animates its representative men throughout their lives This admirable zeal to discover truth and to make it prevail, the profession of dentistry must emulate—indeed already emulates In this zeal is to be found, on the one hand, evidence that the profession is entitled to call itself liberal, and, on the other, security for steady growth and improvement."

He furthermore laid emphasis on the importance of following the example of the medical profession in offering gratuitous practice as a means of demonstrating with singular force the true liberality of the profession And he urged the establishment of gratuitous dental departments in public hospitals, children's asylums and reformatory schools, with the actual labor of such services falling chiefly upon young practitioners, who might, however, be supervised by older men And, finally, he pointed to a common attribute of good physicians and surgeons in their zeal for teaching "The constant desire and purpose on the part of its members

to teach, to impart to all any peculiar knowledge which each may acquire, is," he declared, "one of the principal distinctions between a liberal profession and a trade. Dentistry would have no claim to be called a liberal profession did not its practitioners manifest the zeal for teaching."

The words of advice which President Eliot uttered in 1878 expressed a policy which has characterized the Harvard Dental School for decades. No school in the University has had teachers who have shown a greater zeal for teaching and who have given to so great a degree, gratuitously, their services to the instruction of oncoming members of their profession. They have engaged, likewise, in the establishment and maintenance of what in a general hospital is known as an outpatient department—a place where persons unable to pay may receive free treatment. And in recent years there has been a growing interest in the application of methods of research to the solution of problems which the dentist is constantly meeting. It was very gratifying to President Eliot that these admirable qualities of character and these generous services were for many years quietly and modestly manifest in members of the Faculty of the Harvard Dental School. Repeatedly at meetings of the combined faculties of medicine and dentistry the President mentioned them with warm appreciation. And in one of his last public speeches, made at the Dental School in 1925, when he was ninety-one, he referred to the greatly improved standing of the dental profession among the professions as "one of the most striking changes in public opinion" that he had witnessed during his seventy years of observation of educational progress.

III

One of the many instances of the insight and persistence of President Eliot is found in his repeated urging of an interest in what may be called community medicine. In his Report of 1882-83 he wrote:

'The University has no professorship of public health or preventive medicine—a modern subject of great importance which can be properly dealt with only through an endowed professorship because the professor if properly devoted to his subject would be cut off from private practice. It would be a great service to humanity to divert even a tithe of the money annually given to charities of pauperizing tendency towards the promotion of medical teaching and research.'

Again the next year he drew attention to the desirability of a professorship of Hygiene and Public Health. This was an aspect of medicine which he repeatedly referred to and emphasized as the years passed. Only in 1897-98, however, did hygiene become for the first time in the history of the Medical School a required study. The course was largely concerned with the sani-

tation of our environment, with relatively little emphasis on the hygienic aspects of preventive medicine as applied biology. Indeed, it was not until the appointment of Milton J. Rosenau as Professor of Preventive Medicine and Hygiene, in 1909, that the students were really taught in the way in which President Eliot appeared to have dreamed in his early projections of plans for large-scale protection against disease. The clearest expression of these early views was voiced at the dedication of the new buildings of the Harvard Medical School in 1906. He then ventured to predict that in years to come medicine would "deal more extensively than in the past with preventive medicine, or in other words, with the causes of disease as it attacks society, the community, or the state, rather than the individual. The object in view will be not only to arrest or modify a malady which has appeared in the body of the patient, but, as in the recent case of yellow fever, to learn how the disease is communicated and how to prevent that communication. The study of mitigations, remedies and cures is to continue, but the study of the causes of disease and the means of prevention is to be greatly developed. The function of the nineteenth century physician will continue, and indeed will become more effective through a better knowledge of the forces which may be made to act upon his patient both from within and from without, but another sort of physician will be at work in the twentieth century preventing the access of epidemics, limiting them when they arrive, defending society against bad food and drink, and reducing to lowest terms the manifold evils which result from the congestion of population. The explorers and pioneers in medical science must be encouraged to press on their patient work of analyzing all the processes which accompany disease, in order that they may learn their actual sequences. Only through the knowledge of these sequences can real control over disease be certainly gained. And this work will be endless, for civilization involves constant changes in the environment of the human race, and it is on medical science that the race must depend for protecting it from the new dangers which accompany each novel environment. The medical scientists being provided and furthered, medical education must also train large bodies of men to clear and cultivate the regions through which the pioneers have made trails, or, in plainer words, to apply to millions of men and women in all sorts of climate and environment the discoveries of the scientists."

During President Eliot's eighty-fourth year, at a meeting of the Harvard Medical Alumni Association, he remarked:

One of the previous speakers alluded to my interest in preventive medicine. I have taken a strong interest in that branch of medicine because that

phrase covers an immense new service of the medical profession to the community, and much future happiness for the profession itself. To prevent evils and wrongs on a large scale by one's own personal wisdom and diligence gives even greater satisfaction than to cure individual cases of suffering from evils or wrongs, and the good done to the community by prevention is broader and ampler than the good done by curing."

The very important place which preventive medicine occupied in President Eliot's thinking is revealed by his allusion to it, in his address, "The Religion of the Future," as one of the prominent aspects of the service of man to his fellows. Among the social functions of religious activity he included the protection of humanity against suffering and disease, and especially the efforts of the medical profession directed toward applying medical science to the betterment of man's estate. "The men who do such things in the present world," he declared, "are ministers of the religion of the future."

IV

In the spring of 1907, a small group of students and recent graduates at the Harvard Medical School, who were considering how they could be of greatest service to humanity in the use of their professional training, conceived the idea of establishing a center for hospital practice and medical instruction in China. At the suggestion of Professor E. C. Moore, the proposal was brought to the attention of President Eliot, who consented to become the President of a Board of Trustees. On November 10, 1908, he addressed a letter to Drs. H. P. Wolcott and A. T. Cabot of the Harvard Corporation, to Drs. W. T. Councilman and H. A. Christian and myself of the Medical Faculty, and to Professor E. C. Moore of the Faculty of Arts and Sciences, asking us if we would serve with him on the Board. We all consented. In his letter the President wrote: "I believe the young men are thoroughly in earnest, and that it is a competent group. They propose to have small salaries for themselves—such as missionaries now receive—and to devote themselves wholly to teaching and gratuitous medical and surgical practice among the Chinese." On February 13, 1909, our Faculty of Medicine formally voted to approve and give moral support to the new enterprise.

In order to learn more exactly the conditions in China that would have to be met, Dr. M. R. Edwards, one of the group of young graduates, was sent there to make a survey. The information which he gathered pointed strongly to Shanghai as the best center for the location of a school. At a meeting of the Trustees in April, 1911, Dr. Edwards outlined the results of his trip and stated that enough money had already been assured to allow a favorable start toward realizing the plans. At that time Dr. M. J. Rosenau, Dr. W. S. Whittemore and Mr. Charles

Francis Adams were added to the Board of Trustees. In November, 1911, the venture was definitely launched, and four of the six members of the faculty were in Shanghai.

At that time President Eliot started on his trip around the world to study conditions which might be favorable to the establishment and the preservation of international peace. In the report which he submitted at the end of his trip, in 1912, he declared that the gift of Western medicine and surgery to the oriental populations would be one of the most precious things that Western civilization could do for the East. "To spread through the East," he wrote, "the knowledge of Western medicine and sanitation by building and conducting good hospitals, dispensaries, and laboratories for medical diagnosis, establishing boards of health, and providing defenses against plague, cholera, smallpox, and tuberculosis, is the surest way to persuade intelligent people in the East that they may expect much good from the inductive philosophy of the West acting in combination with the Christian religion in its simplest forms." And again, "Here, then, is a great gift that the West can make to China,—scientific medicine and surgery."

Any Western organization which desires to promote friendly intercourse with an oriental people can do nothing better than contribute to the introduction of Western medicine, surgery, and sanitation into China. The field for such beneficent work is immense, the obstacles to be overcome are serious but not insuperable and the reward in the future comparative well-being of the Chinese is sure. The Chinese people are too intelligent not to trace practical beneficence to its spiritual sources, and to draw all the just inferences." From these declarations it is clear that President Eliot returned from his journey well prepared to continue his interest in the venture undertaken by young Harvard medical graduates at Shanghai.

The Harvard Medical School of China continued in existence until 1917. The Rockefeller Commission, which, after studying the medical situation in China, reported in 1914, declared that the work of the School was "excellent," and praised in highest terms not only the arrangements for teaching but also the management of the small hospital which it controlled. The Commission advised that the Rockefeller Foundation establish a medical school at Shanghai, because of the population and wealth centered there, and it thus confirmed the judgment of those responsible for the location of the Harvard enterprise in that city. But the Great War changed all these generous projects. When by the clash of many nations conditions in this country and throughout the world became unsettled, it was difficult to raise the money required to keep the School developing as it should. In 1917, the Rockefeller Foundation agreed to take over the School, with the ex-

pectation then that it would become the nucleus of a new large medical center at Shanghai, as had been recommended. At the end of the War, however, the interests of the Foundation were involved in urgent European problems, and to the regret of all concerned the plan had to be surrendered.

During the five brief years of the existence of the Harvard Medical School of China, I had the privilege of working with President Eliot at the monthly meetings of the Executive Committee of the Trustees. As I look back upon the experience, the outstanding memories are those of his insistence on the maintenance of high standards of medical education from the start, in spite of all the difficulties which arose when the application of such standards was enforced; his devotion to the welfare of the China School and to the group of earnest young graduates of our School who were engaged in that remote missionary enterprise, and his remarkable grasp and memory of details—even though the period of his service included his eightieth birthday. He secured two sums of money of considerable amount which later, after the School ceased to exist, were turned over to the Corporation of Harvard University to be used for scholarships in the Peking Union Medical School. Before going to that School as its Dean Dr. Henry S. Houghton was the Dean of the Harvard Medical School of China in Shanghai. In his report of 1916 he summed up the contributions which the Harvard venture had made. It had justified its existence; he maintained in establishing the practice of permitting postmortem examinations to be made in China, in training for the first time in history well-educated young Chinese women to become nurses, and in carrying on instruction in the medical sciences, without compromise in conformity with the standards of high-grade medical schools in America and elsewhere. It was in this last respect that the Executive Committee found President Eliot as firm in adhering to his ideals as he had been forty years before, when he first became the President of the University.

V

An account of President Eliot's services to medicine would not be complete if it did not mention his valiant and determined defense of animal experimentation against the attacks of the antivivisectionists. Such attacks were not uncommon in Massachusetts in the first years of the present century, when narrowly restrictive legislation was attempted. In 1900 he appeared before a Legislative Committee, which was holding a hearing on a proposed hostile bill, and argued against the licensing of "vivisectors." He pointed out that the relatively few men engaged in medical research were at the head of their respective branches of medicine and that no one was competent therefore,

to examine them and award them a certificate of qualification. His own experience had given him the right to say that the progress "recently made in medical research is one of the most extraordinary achievements of the 19th century." "Such research is absolutely the most humane of human occupations," he affirmed, "because it has prevented suffering and death on a great scale, and because it promises to achieve in the future still greater triumphs."

What President Eliot in a letter to me called "the perverse intellectual habits of the antivivisectionists" led them to indict him as a cruel man. In a public speech in New York a prominent woman member of the New England Antivivisection Society asserted that he "had allowed his faithful horse his life-long friend and servant, to be given over to torture—his body filled with poison, and his last years ended in suffering and death." I sent the quotation to the President, remarking that the last years of the horse could not have ended otherwise than in death, but asking if the rest of the charge was true. The answer was characteristically factual. He had given a mare, judged by the veterinarian to be hopelessly lame to the Bussey Institution for use in making antitoxin. "The mare," he continued, "promoted a good service for a year and a half, recovered from her lameness and brought a fair price when Dr. Smith sold her—the price being credited to the Bussey Institution. Those are the facts. I do not know how the mare's last years were passed. I had owned her possibly three years, so there is a good deal of romance in Mrs. —'s statement. The whole transaction struck me as very satisfactory, both to me and to the mare."

In 1909 when President Eliot was invited to give the Ether Day address at the Massachusetts General Hospital, he brought substantial moral support to the practice of using lower animals for experimental purposes. In doing so he cited in detail evidence to settle three doubts of its value that he had heard expressed. The first doubt concerning the utility of animal experimentation for medical practice he resolved by enumerating the gains made in the treatment of diphtheria, meningitis, puerperal fever, the plague, tuberculosis, and other diseases of man and animals. Not only did he stress actual achievements but he laid strong emphasis on the legitimate hope which these triumphs warranted, hope that the methods effective in the past would, if continued, assure future advances in medical knowledge and power. The second doubt, as to whether biological research through experiments on animals is justifiable when the results obtained may not have immediate practical value, he countered by citing many instances in the progress of physics and chemistry, in the study of zoölogy and other sciences, which, though seemingly useless and impractical at the time, became later of very great importance for human welfare—among them the

x-rays, the ophthalmoscope, the chemical discoveries of ether and chloroform, and the breeding habits of mosquitoes

It was in meeting the third doubt, related to the question as to whether truth seeking in biology is commendable, even with the help of anesthesia and asepsis, when the research must be conducted at the expense of the comfort, joy or life of animals, that President Eliot was most insistent. He pointed out that the use of animals for the service of man was recognized throughout the civilized world and that such use in the advancement of medical and biological knowledge was thoroughly consistent with human experience and customs

"If the educated public," he wrote, "could see clearly the immense benefits to mankind which have already come and may reasonably be expected to come in much larger amount from the experiments on animals which are necessary to the progress of medical research, if the public could only realize the saving of human suffering and woe which has already resulted and is sure to result in still greater proportion from the sacrifice of a very limited amount of animal comfort and joy, the world would hear nothing more of objections to medical research

What mother could fix a limit to the number of times a comfortable horse should be bled moderately, or to the number of guinea pigs that should be sacrificed, in order to save her baby attacked by diphtheria? The tenderhearted men and women who object to animal experimentation have no vision of the relief of human beings from agony and woe which has come out of animal experimentation. If they had any such vision, they would themselves manifest extraordinary cruelty and inhumanity in opposing medical research in their present blindness they attribute delight in inflicting suffering to the patient, far seeing, and far hoping seekers for biological truth"

And, finally, he struck a note for freedom of research. "The civilized world," he said "has come to believe in freedom of inquiry in all fields as the best means of progress in knowledge in manners, and in righteous living. Now the field of inquiry from which, within the last sixty years, mankind has received the largest visible, tangible, concrete, demonstrable benefits is the field of medical research applied in the medical and surgical art, and in sanitary science. If freedom of inquiry be in general expedient and righteous should not inquiry be free in this most productive of all fields? To secure and maintain this freedom against the assaults of ignorance and misdirected sentimentality it is only necessary that the public should know what medical research has done and is likely to do"

In the later years of his life President Eliot displayed characteristics which we are accustomed to associate with the prophet or the seer. Messages of warning, exhortation or instruction he uttered in occasional addresses or sent forth in published letters and articles. Thus he expressed his opinions about "the woman that

will survive," "the road to industrial peace," "the religion of the future," "the next American contribution to civilization," "probable future causes of international war," "the future of medicine." This is only a partial list of his prophesyings. And, although he once said that he was "very much of the mind of James Russell Lowell, 'Don't never prophesy unless ye know,'" he felt that it was possible to draw some safe inferences with regard to the future from what had been seen in the past, "and a keen observer," he believed, "can often see a few signs of what is coming, because future events, if not too remote, do give signs of their coming." As we look back over his relations to the Medical School and medical education we can see that the President was a prophet throughout the forty years of his administration—a very practical and efficient prophet, who foresaw the next steps needed for closer adjustments of medical instruction to the growth of knowledge, to the better care of patients, and to the promotion of public health, and who bent his energies toward bringing to pass what his clear vision had foreseen. It was the rare combination of insight, understanding, thoughtful projection of reforms, and thereafter patient insistence on their accomplishment, that resulted in the revolutionary changes in medical education which he achieved.

He had a high ideal of the services of our profession to society, and nearly forty years ago he disclosed his vision of the future of those services

"The medical profession has before it an entrancing prospect of usefulness and honor. It offers to young men the largest opportunities for disinterested, devoted and heroic service. The times are past when men had to go to war to give evidence of endurance, or courage, or capacity to think quickly and well under pressure of responsibility and danger. The fields open to the physician and surgeon now give ample scope for these lofty qualities.

"The times are past when the church alone asked men to devote themselves patiently disinterestedly, and bravely to the service of their fellow men. The medical profession now exhibits in highest degree these virtues. Our nation sometimes seems tempted to seek in war—that stupid and horrible savagery—for other greatness than can come from vast natural resources, prosperous industries, and expanding commerce. The pursuits of peace seem to pall for lack of risk and adventure. Would it might turn its energies and its longing for patriotic and heroic emotion into the immense fields of beneficent activity which sanitation preventive medicine, and comparative medicine offer it! There are spiritual and physical triumphs to be won in these fields infinitely higher than any which war can offer, for they will be triumphs of construction and preservation not of destruction and ruin. They will be triumphs of good over evil, and of happiness over misery."

FREQUENCY OF CANCER IN THE INSANE*

BY SHIELDS WARREN, M D † AND MYRTLE M CANAVAN, M D †

BUT a few data are available relating to the occurrence of cancer in insane patients. A few statements have found their way into the literature that cancer is less frequent among the insane than among the general population, and this has been previously ascribed to the simple diet, the routine existence of the inmates of insane hospitals, or other less obvious factors.

Thus in the report for 1909 of the Commissioners in Lunacy for England and Wales we read "There remains one morbid condition (cancer) which is responsible for an increasing number of deaths in the general community, from which it would almost appear as if the insane enjoyed some immunity."

Scattered studies have been made without any definite conclusions. One of the most extensive reports is that of Hahnemann¹, based on the deaths among cases of endogenous psychoses from St Hans Hospital and the State Hospital for Mental Disease in Denmark. The per cent of cancer deaths among 3,052 deaths in these hospitals from 1915 to 1927 was 5.51, whereas the percentage of cancer deaths in the total deaths in the community was 15.11. At all ages recorded and in both sexes the cancer deaths among the insane were strikingly low. However, his data show that among the insane population the deaths increase rapidly in the earlier years, the peak occurring in the decades 45-55, whereas in the general population the peak occurs in the decades 75-85. While this does not necessarily vitiate Hahnemann's figures, as he compares the insane with the general population by age groups, it does suggest unusual prevalence of some disease. His table XIII shows that at least one frequent disease is tuberculosis. Laursen² criticizes Hahnemann for the inclusion of exogenous psychoses in this material, and stresses the possible importance of constitutional type in cancer.

Chevens³, among 768 deaths in patients with endogenous psychoses, found 5.1 per cent of cancer deaths, closely paralleling Hahnemann's figure of 5.5 per cent. Moreover, his lowest percentage occurred among schizophrenics, as did Hahnemann's. This group shows a young average age at death.

In England and Wales from 1920-28 the death rate from all causes in those over 15 years of age was six times as high in the institutional-

ized insane as in the general population, while the cancer death rate was only twice as high⁴. The abnormally high rates for general paralysis and tuberculosis may explain the low relative cancer rate.

A higher percentage of cancer deaths (9.7) was found by Lind⁵ among 215 autopsies on patients of two Australian insane hospitals.

Pool⁶ reported 4.9 per cent cancer deaths from the Ramhill Hospital, England, from 1904 to 1928, among 3357 autopsies. Among the cancer deaths were included cases of primary intracranial tumors. Over half the cases were of gastro intestinal cancer. He quotes Hanf as finding 13 per cent cancer deaths among all autopsies from 1903-25 to the Charité Hospital, Berlin.

Lombard in the special report⁷ of the Massachusetts Department of Public Health in 1925 found 36 cancer cases per annum in the insane, instead of the expected 174, on the basis of an incomplete study.

In Zurich, 2000 autopsies on insane patients included 6.5 per cent malignant disease cases, of which 18 were gliomas⁸.

Practically all the reports show an apparent infrequency of cancer among the insane population. In general the insane show about 5 per cent proportionate cancer mortality, about one-third that of the general population. However, in most reports there are inadequate data for comparison and the great prevalence of other diseases (infections, etc.) in the insane offers one reason for a low cancer rate.

One of the few to attempt to avoid the pitfalls inherent in proportionate mortality rates is Opsahl⁹, who found in 17 Norwegian hospitals for the insane 244 deaths from cancer among 7000 fatalities (3.5%). The diagnosis was verified by autopsy in 170 of the deaths. On the basis of adjusted figures, however, he finds no real difference between the cancer mortality rate of the total population and the insane population. Table I, taken from his article, illustrates this point.

TABLE I (From Opsahl)
DEATHS FROM CANCER PER 10,000 LIVING INDIVIDUALS
PER YEAR

	40-50 Years	50-60 Years	60-70 Years
In the mean population	ca. 10.0	24.0	52.0
In insane hospitals	12.4	33.0	63.9
In schizophrenia	11.5	31.7	67.4
In other insane patients	15.0	36.8	57.7

However, Opsahl's figures are readily brought into line with the others when we note that he is comparing the annual death rates for can-

x-rays, the ophthalmoscope, the chemical discoveries of ether and chloroform, and the breeding habits of mosquitoes

It was in meeting the third doubt, related to the question as to whether truth seeking in biology is commendable, even with the help of anesthesia and asepsis, when the research must be conducted at the expense of the comfort, joy or life of animals, that President Eliot was most insistent. He pointed out that the use of animals for the service of man was recognized throughout the civilized world and that such use in the advancement of medical and biological knowledge was thoroughly consistent with human experience and customs

"If the educated public," he wrote, "could see clearly the immense benefits to mankind which have already come and may reasonably be expected to come in much larger amount from the experiments on animals which are necessary to the progress of medical research, if the public could only realize the saving of human suffering and woe which has already resulted and is sure to result in still greater proportion from the sacrifice of a very limited amount of animal comfort and joy, the world would hear nothing more of objections to medical research

What mother could fix a limit to the number of times a comfortable horse should be bled moderately, or to the number of guinea pigs that should be sacrificed, in order to save her baby attacked by diphtheria? The tenderhearted men and women who object to animal experimentation have no vision of the relief of human beings from agony and woe which has come out of animal experimentation. If they had any such vision, they would themselves manifest extraordinary cruelty and inhumanity in opposing medical research in their present blindness they attribute delight in inflicting suffering to the patient, farseeing, and farhoping seekers for biological truth"

And finally, he struck a note for freedom of research. "The civilized world," he said, "has come to believe in freedom of inquiry in all fields as the best means of progress in knowledge, in manners, and in righteous living. Now the field of inquiry from which within the last sixty years, mankind has received the largest visible tangible concrete, demonstrable benefits is the field of medical research applied in the medical and surgical art, and in sanitary science. If freedom of inquiry be in general expedient and righteous should not inquiry be free in this most productive of all fields? To secure and maintain this freedom against the assaults of ignorance and misdirected sentimentality it is only necessary that the public should know what medical research has done and is likely to do"

In the later years of his life President Eliot displayed characteristics which we are accustomed to associate with the prophet or the seer. Messages of warning, exhortation or instruction he uttered in occasional addresses or sent forth in published letters and articles. Thus he expressed his opinions about "the woman that

will survive," "the road to industrial peace," "the religion of the future," "the next American contribution to civilization," "probable future causes of international war," "the future of medicine." This is only a partial list of his prophesyings. And, although he once said that he was "very much of the mind of James Russell Lowell, 'Don't never prophesy unless we know'," he felt that it was possible to draw some safe inferences with regard to the future from what had been seen in the past, "and a keen observer," he believed, "can often see a few signs of what is coming, because future events, if not too remote, do give signs of their coming." As we look back over his relations to the Medical School and medical education we can see that the President was a prophet throughout the forty years of his administration—a very practical and efficient prophet, who foresaw the next steps needed for closer adjustments of medical instruction to the growth of knowledge, to the better care of patients, and to the promotion of public health, and who bent his energies toward bringing to pass what his clear vision had foreseen. It was the rare combination of insight, understanding, thoughtful projection of reforms, and thereafter patient insistence on their accomplishment, that resulted in the revolutionary changes in medical education which he achieved.

He had a high ideal of the services of our profession to society, and nearly forty years ago he disclosed his vision of the future of those services

"The medical profession has before it an entrancing prospect of usefulness and honor. It offers to young men the largest opportunities for disinterested, devoted and heroic service. The times are past when men had to go to war to give evidence of endurance, or courage, or capacity to think quickly and well under pressure of responsibility and danger. The fields open to the physician and surgeon now give ample scope for these lofty qualities

"The times are past when the church alone asked men to devote themselves patiently, disinterestedly, and bravely to the service of their fellow men. The medical profession now exhibits in highest degree these virtues. Our nation sometimes seems tempted to seek in war—that stupid and horrible savagery—for other greatness than can come from vast natural resources, prosperous industries, and expanding commerce. The pursuits of peace seem to pall, for lack of risk and adventure. Would it might turn its energies and its longing for patriotic and heroic emotion into the immense fields of beneficent activity which sanitation, preventive medicine and comparative medicine offer it? There are spiritual and physical triumphs to be won in these fields infinitely higher than any which war can offer for they will be triumphs of construction and preservation not of destruction and ruin. They will be triumphs of good over evil, and of happiness over misery."

about 40 per cent as much as in the state as a whole in both males and females. If we were to exclude in calculation of our proportionate mortality rates the deaths among infants and children, the discrepancy would be even greater.

In an effort to avoid the errors that may be inherent in the proportionate mortality rate and to provide a control series of a fairly comparable type, we have compiled a random group of autopsies from the large general hospitals of Boston. The method used was to match so far as possible each case in the insane series with one in the control series. The great bulk of the control cases were taken from the autopsy files of the Boston City Hospital. Some supplementary cases were taken from the files of the Massachusetts General Hospital, the Peter Bent Brigham Hospital and the Department of Pathology of the Harvard Medical School.*

In practically all instances not only were the autopsies matched by age group and sex but by year of autopsy as well although in a few instances in order to complete the older age groups it was necessary to take some cases that were autopsied in earlier years. This control group probably represents a fairly comparable social level to the cases autopsied in the state insane hospitals and is reasonably representative of the various types of disease. Possibly the number of autopsies on cases of tuberculosis is low in this control series inasmuch as special institutions exist for the care of this disease.

The exact method of building up the control series of table IV was as follows. After determining the age group and sex of the autopsies for the insane hospital group, say for the year 1925 the 1925 autopsy files of the Boston City Hospital were gone through noting the cause of death and presence or absence of malignancy in each case of suitable age and sex as it was encountered in running through the volumes of the files. In this way any possibility of unconscious selection of cases was ruled out. The autopsies in both the insane hospital group and in the general hospitals were presumably done with the same degree of care and skill so that the cases of malignant disease as recorded may be regarded as a fair reflection of the number actually present. The results are presented in table IV.

The fairly close parallelism of the results of our two types of control that from the number of cases of cancer calculated from the proportionate mortality rate of 1924 and that from the number of cases of cancer obtained from the autopsies in the various general hospitals, suggest a substantial accuracy of these two controls in representing the incidence of malignant disease in the general population. Of course it

must be admitted that the group is not large enough to be regarded as accurate, but none the less it apparently provides a satisfactory sample. If we select the 1931 Massachusetts proportionate mortality rate for cancer in place of that for 1924 the total figure for the two types of control series check almost exactly. In the minds of some the increased cancer mortality represents the effect of more accurate diagnosis, and if this be so, the 1931 rates are more correct than those for 1924 and the discrepancy be-

TABLE IV
FREQUENCY OF MALIGNANT DISEASE AMONG AUTOPSIED CASES IN INSANE AND GENERAL HOSPITAL PATIENTS

Age Group	Sex	Insane Series			Control Series

tween the amount of cancer in the insane and in the general population even more striking.

As a further check on our series of autopsies, we have obtained through the courtesy of Dr. William Freeman the number of cancer cases encountered among 2340 autopsies at the Worcester State (insane) Hospital. The cancer cases total 126, or 5.4 per cent, omitting primary intracranial tumors.

Intracranial tumors are excluded from this group as they naturally weight the material very heavily. Thus there are encountered in this present autopsy series 27 cases of primary intracranial tumors in males and 11 in females. These include meningiomas, pituitary adenomas, acoustic neuromas and gliomas. We have excluded these tumors because the majority of them are not malignant in the pathologic sense, the only ones justifiably considered as malignant tumors being certain of the gliomas. The existence of an intracranial tumor might well predispose toward admission to an insane hospital. The incidence of all types of intracranial tumors in our autopsy series from the insane hospitals is 1.4 per cent. Morse¹¹ gives the percentage of brain tumors seen in insane hospitals

*Note. We are indebted to Dr. Frederic Parker, Jr., for the privilege of utilizing the autopsy material of the Boston City Hospital to Dr. Tracy B. Mallory for that of the Massachusetts General Hospital and to Dr. S. B. Wolbach for that from the Peter Bent Brigham Hospital and the Harvard Medical School.

cer per 10,000 living institutionalized insane and normal persons. If we take the death rate of Norway¹⁰ as a whole for 1930 we find it to be 105 per 10,000 living, whereas the death rate for insane hospitals for the year 1930 is 487 per year, or nearly five times as much. Thus his figures are not fairly comparable. Moreover, the proportionate mortality from cancer in Norway for 1930 is 11.5 per cent. The proportionate mortality given by Opsahl for the insane is 3.5 per cent. Therefore, it is apparent that instead of being at variance with the findings of other observers his findings actually parallel them. In fact, if we consider 1930 to be a fair year (and study of available reports justify this), the death rate in the insane in Norway is so much higher than in the general population that the cancer rates given in table I for the insane should be divided by four or five in order to give a true comparative picture. The high incidence of cancer of the stomach (102 out of 223 carcinomas) in Opsahl's series is very striking.

Our attention was first called to cancer among the insane by the increasing frequency with which surgical specimens from patients in the state insane hospitals were received for diagnosis at the laboratory and proved to be malignant. This increase is probably due to the generally awakened consciousness of cancer, or at least a more definite interest in this disease.

Since 1914 one of us (M. M. C.) has performed practically all of the autopsies in cases of sudden or unexpected death at the various state insane hospitals. The advantage that material of this type possesses for the demonstration of malignant disease in its early as well as its advanced stages, and for giving a fair sample of the hospital population, is obvious. We have therefore, studied the proportion of cancer found among the 2,627 autopsies of this type performed from 1914 through 1930. The cancer cases number 114, or 4.3 per cent. Owing to the smallness of the sample, no segregation according to type of mental disorder has been attempted, although practically all types are represented. The majority of the cases had been inmates for a considerable period of time, and may be regarded as fairly subject to institutional environment.

In table II are presented the causes of death in a portion of this group.

Pulmonary disorders account for 29 per cent of deaths, nearly twice as much as in the general population. Colitis is also abnormally frequent, because of occasional epidemics of dysentery.

Table III presents the actual and calculated cases of malignancy in this series. We have used the Massachusetts proportionate cancer mortality rate for 1924 (the year on which our autopsy material centers) in this calculation. The difficulty of obtaining a satisfactory norm

for the expected cancer incidence in the insane population is great. We are aware of the danger in attempting to draw conclusions based on the use of proportionate mortality rates. Unfortunately practically all the published reports have used these alone.

Table III brings out an apparent infrequency of cancer among the insane population—

THE COMMON NATURE OF PEPTIC ULCER AND COLITIS*

BY WILLIAM A. EVANS, JR., M.D.†

IT is often said that no final or entirely satisfactory classification of diseases can be made that is not based upon a well-defined and well-established etiology. Failing that, however, varying degrees of success are achieved in the classification and conception of disease entities. There is a satisfactory concept of a disease process when the concept is not merely a static one but one which contains the earliest manifestations of the disease as well as its fully developed and final forms. Not only that but the concept allows one to recognize a disease process as identical, though it may occur in different organs with vastly different manifestations. The concept of tuberculosis, for example, is nicely satisfying because it contains the earliest recognizable manifestations such as afternoon fatigability or a small area of infiltration in the upper lung fields as well as the final stages with massive cavitation and hemorrhage. Furthermore it is possible to recognize as identical processes a tuberculous infection of the lung and an infection of bone. The unity of this concept has, of course, been largely due to the discovery of the tubercle bacillus as the etiologic factor. However, the concept of malignant disease is equally satisfying, though the etiology is unknown, because of these same two elements, namely, the recognition of the disease in its earliest as well as in its latest stages as a progressing, dynamic process and the recognition of the disease in various organs of the body as identical. The attempts at the classification of renal disease have emphasized this necessity of considering the element of time and progression. The proper concept of a disease entity must be something more than an array of static symptoms.

It is a fact perhaps not sufficiently realized that the fashion of diagnostic nomenclature is often dependent upon the fashion of diagnostic methods. This has been particularly true for diseases of the gastrointestinal tract. In Germany, for example, where the gastroscope is in general use and a routine study is made of the gastric mucosa by means of the fluoroscope and a small amount of barium paste, the diagnosis of gastritis is made with the greatest frequency. In this country that diagnosis is hardly respectable and ulcer is considered the organic lesion of chronic dyspepsia. However, it is interesting to note that some years ago, when pathological studies were being made at the Mayo Clinic on material obtained from operations on the stomach and duodenum, the diagnosis of duodenitis came into being. If some organic lesion is not recognized the diagnosis becomes hyperchlorhyd-

ria, or if not that, gastric neurosis. This sort of nomenclature is very unsatisfying inasmuch as the name of a pathologic lesion or dysfunction is used to indicate a disease process. The proper concept of a disease process cannot be contained in the name of a pathologic lesion because the concept of development and progression is precluded. Gastric ulcer with small letters may mean anything from acute lesions following operation in the diencephalon as described by Cushing to the ulceration of an early gastric carcinoma. Written with capitals as the name of a disease it limits the conception of the disease to a single static pathologic lesion. The disease Gastric Ulcer cannot be said to exist until a gastric ulcer is demonstrable, though in all probability the disease does begin before there is any ulceration. There is said to be a typical history for peptic ulcer and that is true, but it has been the experience of everyone that a perfectly typical history may be obtained and yet no ulcer may be demonstrable either by x-ray or at operation. For example, Deaver and Burden¹⁰ have written "Every surgeon many times has had the experience of operating on a patient who exhibited the characteristic symptoms of ulcer but no ulcer by most thorough search could be demonstrated." It has even been fairly well demonstrated that the symptoms of the disease in question are due not to the ulcer but to dysfunction of the pylorus.¹¹ However careful we may be, the name of the disease will continue to force our attention on the pathologic lesion as identical with the disease and the source of all symptoms, whereas, in all probability, ulceration is but one of many equally important manifestations of the disease process.

This disease (or group of diseases) can be well defined by the following characteristics

- (1) Chronicity
- (2) Periodicity
- (3) Hypersecretion
- (4) Dysfunction of smooth muscle action
- (5) Non-specific inflammation with ulceration
- (6) A large psychic element related to a constitutional bias

This disease, I hope to show, may affect various portions of the gastrointestinal tract and perhaps the respiratory tract as well. Naturally the disease is not always present with the characteristics fully developed. It is necessary to include in the disease concept the earliest, or what von Bergmann⁹ would call the larval forms, although it seems unnecessary to anticipate a metamorphosis in the ultimate development of the disease process.

The manifestations of this disease in the upper gastrointestinal tract are recognizable in chronic gastric and duodenal ulcer, chronic gas-

as 18 In a group of 1,066 autopsies from the laboratory of the New England Deaconess Hospital, where a fair amount of neurosurgery is done, we estimate only 0.8 per cent intracranial tumors Bailey¹² quotes Wood as giving the incidence of brain tumors as 1.8 per cent of all tumors, which would be far lower if compared with deaths from all causes, of which our series consists

We therefore feel justified in excluding the intracranial tumors as they would constitute 25 per cent of our cancer deaths However, even if we do include them, the incidence of cancer is abnormally low in our insane series, 152 cancers and intracranial tumors as against 265 expected cancers on the basis of the proportionate mortality rates, or 57 per cent of the expected

That our series is fairly representative of cancer in the insane is shown by table V, which

TABLE V
PRIMARY SITES OF CANCER IN THE INSANE

Uterus	12	16
Others	25	20
Total	114	126

compares the primary sites of cancer in our series and in the Worcester State Hospital series

On the basis of the figures in the literature there is about one-third as much cancer in the insane as in the normal population Our own results are roughly parallel Whether these results are correct only careful study of the insane population will tell Such study is urgently needed

Because of the great variation in total mortality between the insane and the normal population, any satisfactory standardization of the cancer rate is extraordinarily difficult One able statistician, Greenwood¹², who has attempted this, finds that in England and Wales for 1910-12, the rate in the general population was 13.4 per 10,000 and in the institutionalized insane 15.8 per 10,000

If we assume the accuracy of available information, cancer is abnormally infrequent in the insane This might be explained by environment, by heredity, or most likely by the relatively short life expectancy of the insane patient Thus shortened life expectancy may be an intrinsic feature of the disease, or a result of the environment Be this as it may, the insane patient has a definitely shorter period for the development of cancer than has a member of the general population

Still another problem is presented in the determination of what rate to use in the calculation of the expected cancer mortality under these circumstances It is possible that a mortality rate does not best represent the facts but a morbidity rate should be used, or even a rate between the two In a subsequent paper we hope to produce definite evidence on these points

There is no reason to assume that environmental factors are of importance, other than perhaps increasing the amount of respiratory disease Diet may be more monotonous and the conditions of existence less varied, but not sufficiently different from those of the bulk of the population to alter the incidence of cancer

Evidence is accumulating that a constitutional predisposition to cancer, perhaps hereditary, exists Heredity may also be of importance in insanity We must at least consider the hypothesis that the soil best suited for the development of cancer differs from that in which insanity develops

On the basis of information at present available, cancer is definitely less frequent in the insane than in the general population However, we realize the data are as yet inadequate

function other than that of the stomach and pylorus have been described. It is the conception of von Bergmann that the spasm of some small vessel in the stomach is the primary incident in the pathogenesis of peptic ulcer. Evidence of such a vasoneurotic diathesis in patients suffering from ulcer has been found by O. Müller in his microscopic observation of capillary blood vessels. This has been confirmed by Duschl²⁰ who made direct observations on capillaries in the living stomach mucosa. Varying figures are given for the incidence of hyperacidity with ulcer but the most carefully controlled and accurate work appears to be that of Cheney and Bloomfield¹⁴ who showed that in all cases of their series not only was the gastric acidity above the average but the volume of secretion was also above the average for the corresponding age period. However the occasional case of peptic ulcer with normal acidity or even an acidity indicates that excessive secretion is not essential to ulcer genesis. Careful studies of mucous secretion have not been carried out, perhaps largely because of the technical difficulties involved. However Simchowicz¹⁹ states that there is no clear relation between the amount of mucus and the amount of acid. He further states that an increased amount of mucus is the usual finding in gastritis. The significance of gastromyorrhea—whether a secretory neurosis according to Kuttner or a symptom of gastritis according to V. Aldor—suggests the same problem which arises when an excessive amount of mucus is found in the colon^{6 11 13 23 25}

GASTRITIS

Gastritis is a disorder of the greatest importance in an understanding of the chronic diseases of the stomach. Unfortunately it is a diagnosis which though very popular thirty or forty years ago has fallen into general disrepute. This was undoubtedly due to the fact that there was no means of adequately confirming the diagnosis during life and at autopsy the stomach was so disfigured by postmortem digestion that slight inflammatory changes could not be detected. Chiefly in Germany and Sweden the diagnosis has been revived and placed upon a sound basis through frequent use of the gastroscope and a roentgenologic technique designed to reveal details of the gastric mucosa. In this country the term usually refers to those gastric lesions which are secondary to chronic alcoholism, improper mastication, nicotine abuse, chronic passive congestion, nephritis or chemical poisons, but in addition there appears to be a chronic gastritis which for want of a better designation, might be termed primary or idiopathic and which bears a close relation to peptic ulcer.* There is so great a similarity in the

manifestation of the two diseases as to suggest their identity. Konjetzny^{41 43} points out that gastritis has the same periodicity in its manifestations as ulcer. Korbisch⁴⁴ says that gastric hypertony, hypermotility and hyperesthesia are common to both diseases. According to Hohlweg²³ disturbance of motility, particularly at the antrum is common in chronic gastritis. Lemberger⁴⁵ believes the spasmodic and hypersecretory phenomena are parallel in gastritis and peptic ulcer. A number of studies have come from the Mayo Clinic concerning duodenitis which, without much doubt is the duodenal equivalent of the type of gastritis under discussion. Judd³⁵ mentions those cases with a long history typical for ulcer which reveal only duodenitis at operation. This fact has been later repeated and amplified by Hartman and Rivers⁶, Wellbrock⁵, Rivers³ and Hufford²⁷

A point of particular interest is the occurrence of gastric and duodenal inflammatory changes coincident with peptic ulcer. While the reports from many German clinics^{20 27 39 40 46} give the incidence of inflammatory changes a high figure and a number of workers report that some signs of inflammation are invariably present, Walters⁴, on the basis of material at the Mayo Clinic, states that peptic ulcer is a different disease here than in Germany. As an unconfirmed and unlikely statement no great importance can be attached to it but it does suggest the confusion which attends the recognition of inflammatory lesions. It is not alone in Germany but also in France and Sweden²⁷ that emphasis is placed on the association of inflammation with ulcer. On the whole it seems much more probable that there is no significant difference in the disease in different countries but that the inflammatory lesions are found in those countries where they are systematically and diligently looked for. Partly on the basis of Walters' statement, Barclay¹ in his recent book on the roentgenology of the digestive tract minimizes the importance and possibility of recognizing gastritis quite contrary to the views of a great number of roentgenologists headed by a person no less reputable than Forssell. Recently in this country Crane¹⁵ expressed more awareness of the roentgenologist's shortcomings in gastric diagnosis, when he wrote "It is fair to say that in the past roentgenologists have missed many more gastric ulcers than they have found —" Furthermore he is more hopeful for the newer technique when he writes "Certainly we can look forward with eager interest to the development of roentgenologic methods of delineating the rugae of the stomach which, if successful, will, we believe, enable us to recognize gastric ulcer as never before and make good a reputation that has somewhat outrun our capabilities in the past." It is of importance to note that inflammatory changes when they do

*To confuse this form of gastritis with any of the above-mentioned would be as serious an error as to confuse the hydrothorax of tuberculous pleurisy with that of heart failure. This appears obvious but Hauser²⁷ in considering the formation of ulcer wonders that ulcers do not occur in the areas of gastritis surrounding carcinoma of the stomach.

tritis, chronic duodenitis, hyperacidity and probably many forms of gastric neurosis. It is probable, too, that cardiospasm and ulcerations of the lower end of the esophagus belong in this group.

PEPTIC ULCER

Chronic peptic ulcer presents the disease in its fully developed form. The elements of chronicity and periodicity are too well known to mention. What is significant is that these same elements, in fact a history typical for peptic ulcer, may be obtained and yet no ulcer be demonstrable either at operation or by x-ray. In the first edition of Osler's textbook⁵⁸ published in 1892, before the use of x-ray in gastrointestinal diagnosis he states, in discussing the diagnosis of ulcer: "The greatest difficulty is offered by certain cases of gastralgia which may resemble ulcer very closely, as, with the exception of hemorrhage, there is no single symptom which may not be present." It is now known that even hemorrhage is not a distinguishing feature.

In a large clinic one sees not infrequently cases of hemorrhage at some point in the upper gastrointestinal tract when no lesion can be demonstrated by the roentgenologist. Rivers⁶⁴ has discussed these "hemorrhagic focal gastroduodenal lesions" in cases operated upon because of hemorrhage and in which no ulcer was found. He regarded these lesions as infectious gastritis and duodenitis and possible forerunners of chronic ulcer. Korbseh⁶⁵ states that small hematemeses are more commonly seen in gastritis than ulcer, while Konjetzny⁶² describes eight cases with a history typical of ulcer, including hemorrhage, which showed at operation gastritis but no ulceration. Bédère, Moutier and Porcher⁶ have described a case with all the manifestations of ulcer including hemorrhage on numerous occasions in which no ulceration or even inflammation could be discovered at operation.

In the French and German literature one reads, not infrequently, of the "ulcer disease" to describe these cases with all the signs of ulcer but the ulcer itself. Hohlweg²⁸, Steiner⁷⁰ and Renaud⁶¹ have emphasized this distinction and have intimated that gastritis is a significant lesion in this disease. Indeed, Renaud⁶¹ regards gastritis as the essential lesion and ulceration simply a complication. Gray²⁹ reported 250 cases showing the duodenal ulcer symptom-complex, in 32 per cent of which no ulcer could be demonstrated. However, he ascribes tobacco smoking as the etiologic factor in 41 per cent of these and a "constitutional disorder" in 18 per cent.

It seems at this time that without doubt peptic ulcer is not simply a local disturbance of the mucous membrane. The great frequency with which recurrence takes place after surgical removal or medical treatment is sufficient testi-

mony. Emery and Monroe²², in reviewing a large series of cases, state that the evidence indicates that peptic ulcer is a chronic disease in which our present methods of treatment are only palliative. From this point it is not a long step to the conception of peptic ulcer as a constitutional disease. Indeed, constitution is one of the most commonly mentioned aspects of the disease in recent discussions^{24 63 66 67}. The work of Diaper is well known. Hurst³¹ regards a gastric diathesis as the essential predisposing cause of duodenal ulcer. The motor and sensory signs of the diathesis are as obvious in the very early cases as in the late ones and they persist after the ulcer has healed. Furthermore the diathesis is frequently familial, some members showing evidence of the diathesis without ulceration. McVicar⁵⁰ has reported a large ulcer family and Kalk³⁰ gives references to numerous articles in which ulcer families are described. He is of the opinion that the younger the patient the more prominent is the constitutional or hereditary factor, whereas in the older patient the environment plays a more important rôle. In a small series (17) of young (13 to 19 years) patients with ulcers, he found 53 per cent with a definite history of stomach complaints in the family but had reason to believe the percentage would be 75 or 80 per cent if a more accurate history could be obtained.

The importance of environmental factors is well known. Worry and emotional disturbances are commonly recognized as a cause of recurrences. Peptic ulcer may heal under any circumstances conducive to a sense of psychic well-being. It has been frequently demonstrated that rest in bed may be quite as helpful as a strict regimen of diet and alkaline powders. Russ⁶⁰ has described the value of travel and change of residence while Ryle⁶⁷ has recently given a very striking description of a patient with peptic ulcer who, while at home, had suffered pain even under the most rigid regimen, but while mountain climbing in the Tyrol could eat and drink everything without discomfort.

Spasm and excessive acid have long been regarded as among the most important signs of peptic ulcer and likewise of importance in many theories of the pathogenesis of ulcer. Deaver and Burden¹⁰ (also⁵²) for example, believe that a combination of pylorospasm (preventing regurgitation of alkaline duodenal contents) and hyperacidity will produce peptic ulcer. Spasm of the stomach, spasm at the pylorus, excessive peristalsis and excessive secretion are mentioned by Barclay¹ as the indirect ulcer signs which may be recognized with the Roentgen ray. Moutier⁶⁴ has described very graphically the appearance of the stomach examined by means of the gastroscope and has pointed out the hypertonia of the stomach wall, spasm often noted at the cardia or pylorus and the "mucus lake" which is so often seen with ulcer. Manifestations of disturbed smooth muscle

admitted by many observers (Brown¹³ Rosenheim⁶⁵, Friedenwald²⁴ and Zweig⁷⁰) Unfortunately in discussing constitution, there are no objective measurable or demonstrable characteristics to indicate the defect in question. What one usually does is to refer as Draper does, to some measurable characteristic such, for example, as the gonial angle which is assumed to be a constitutional characteristic. Then if there is a correspondence between this characteristic and the disease in question the disease will also be assumed to be constitutional in nature. However there is no reason to suppose that there is any degree of parallelism in the incidence of a larger number of constitutional characteristics. Although the question of constitution remains one of impression unsupported by well-defined evidence, it is perhaps significant that there is a widespread impression of constitutional disorder as a basis for the diseases in question.

The most frequently described aspect of these colon diseases is the manifestation of nervous disorder. It is sometimes pointed out that anyone suffering from attacks of exhausting diarrhea might be entitled to some nervousness, but the nature of the disorder is something quite different from what one sees in tuberculous colitis for example. It appears to be much more a characteristic of the patient's personality than a by-product of some disease process. "Nervousness" is, of course, accepted as one of the most striking manifestations of mucous colitis^{11, 6, 12, 13}. Eggleston²¹, Hunter³⁰, Drucek¹⁵, Jordan³⁴, Barker⁶ and Sherman⁶⁶ have all commented on the neurotic character of patients suffering from spastic colon while Eggleston²¹ and Hunter³⁰ point out that the symptoms are most frequently incidental to some emotional disturbance. Likewise Bastedo⁷ comments on the exacerbation of mucous colitis by strain and fatigue. This feature is no less striking for ulcerative colitis. Rosenheim comments on the signs of an inferior vegetative system in these patients and Zweig mentions their labile nervous system. Even Larson⁴⁶ and also Bergen^{3, 4}, while holding to the infectious nature of ulcerative colitis point to the importance of psychic factors in bringing about relapses. Murray⁵ and later Sullivan and Chandler² have given detailed personality studies of a number of patients showing how closely related attacks are to emotional difficulties. Murray⁵⁵ believes there is a common psychologic make-up in cases of gastric ulcer and colitis characterized by fearfulness, and points to the emotional immaturity of patients suffering from colitis.

SUMMARY

An attempt has been made to enlarge the concept of peptic ulcer as a disease process and to show its relation to the group of non-specific colitides.

It is suggested that the terms pylorospasm,

hyperchlorhydria gastritis (duodenitis) and peptic ulcer represent forms or stages of one disease process in the stomach (duodenum) and that this disease is manifest in the lower intestinal tract through spastic colitis, mucous colitis, catarrhal and ulcerative colitis. A plea is made for a study of gastric dysfunction and pathology which may be present before ulceration takes place.

It is a pleasure to express my gratitude to Prof. E. Grafe and Priv. Doz. Strieck for the opportunity of attending many gastroscopic examinations at University Medical Clinic at Würzburg and to Prof. Henry A. Christian for a number of important suggestions in the preparation of this manuscript.

occur, occur not only in the immediate vicinity of the ulcer but at distant and isolated areas as well. As with so many of the other manifestations of ulcer the question arises as to the primary or secondary nature of the inflammatory lesion. Konjetzny and his followers^{10 47 48}, reviving the views of Cruveilhier, are ardent supporters of the view that gastritis is primary and that ulceration takes place only in an inflammatory area. On the other hand are numerous opponents^{20 27} who are of the opinion that inflammatory changes are entirely secondary and of negligible importance. This is a question which cannot be decided by viewing a disease process in its isolated states, but only when it is viewed as a progression from the earliest to the latest phases. The most significant work of this sort is a recent report by Norpoth⁶⁷ in which three patients are described in whom a diagnosis of gastritis was made upon roentgenologic or gastroscopic evidence and in whom an ulcer developed at a later date, in one case six months later, in another seventeen. It is entirely possible that by close attention to the individual make-up, to the history and to the earliest Roentgen and gastroscopic signs, it will be possible to diagnose the disease "peptic ulcer" before ulceration takes place.

* * * * *

COLITIS

The term colitis is in a state of disrepute almost as sad as that of gastritis. Again the wide variety of dissimilar conditions to which the name is applied and the lack of positive criteria for diagnosis are responsible. There are certain well-defined varieties of colitis, such as tuberculous colitis, bacillary and amebic dysentery, colitis resulting from chemical poisons, nephritis, etc., but in addition there is a group of colon disorders bearing the terms spastic colitis, mucous colitis, ulcerative colitis, catarrhal colitis, etc., which appears to have a definite relation to the diseases described above. Barger⁴ and also Jordan³³ object to the term colitis being applied to these non-infectious diseases but the nomenclature is now so well rooted that it is unlikely that any change will take place.

The four above-mentioned non-specific forms of colitis have been grouped together as representing a view frequently expressed in recent years and one which seems particularly illuminating. Brown¹³, Mallory⁴⁹, Tidy³ and Metz⁵¹ are among those who point to the common character of these disturbances while there are numerous writers who described the transitional stages between two or more of the closely related forms. Ideally these diseases would represent separate entities, one dominated by spastic phenomena of the colon, one by the discharge of mucus, and another by inflammatory and ulcer-

ative lesions, but it is rare that the disease presents itself in so ideal a manner. Usually there are manifestations of all these phenomena in varying degree. For example, Eggleston²¹ says there is excessive mucus in many cases and Drueck¹⁸ in the majority of cases of spastic colitis, while according to Hunter³⁰ mucous colitis may be regarded as an aggravated form of spastic colon. In reporting a large series of cases of mucous colitis, Friedenwald, Feldman and Rosenthal²³ point out that inflammatory changes are at hand in most cases and ulcerative colitis may develop. According to Drueck¹⁸, inflammation frequently occurs in the spastic colon and may terminate in ulcerative colitis. Kuttner⁴⁵ (also¹⁰) holds that colitis ulcerosa indicates the late stage of the disease and in this seems to be supported by the majority of recent German writers.

The relation of the non-specific colon disease to the previously discussed gastroduodenal disease is of particular interest. What appear to be the fundamental phenomena of disturbed muscular function, hypersecretion, non specific inflammation leading to ulceration, and a constitutional bias are common to both groups. It is an interesting speculation of Eggleston's²¹ as to why women are apparently more susceptible to colitis and men to peptic ulcer. Not rarely do both diseases occur in the same individual. A high incidence of bowel symptoms in gastric and duodenal ulcer has been noted by Miller, Pendergrass and Andrews⁵³. Friedenwald, Feldman and Rosenthal²³ (also³²) found 5 per cent duodenal ulcer, 3 per cent gastric ulcer and what they term gastric dyspepsia in 64 per cent of their five hundred cases of mucous colitis. Bockus, Bank and Wilkinson¹¹ found cardiospasm in two and pylorospasm in ten out of fifty cases. Baigen and Rivers⁵ found peptic ulcer sixteen times in their series of five hundred cases of ulcerative colitis and state that there was a "definite parallelism between the severity of the symptoms of the associated conditions". They also mention that there is some "presumptive evidence of allied etiology". The non specific character of the inflammation in the upper and lower portions of the intestinal tract seems to be rather generally agreed upon. Rosenow's⁵⁰ views in regard to peptic ulcer and Barger's³ for ulcerative colitis have not received any widespread support^{1 60 59 13}. The frequency of the acute and chronic infections as the apparent precipitating factor in many cases is given by Larson⁴⁰ as evidence of the infectious nature of ulcerative colitis but when it is realized that infections may precipitate symptoms in such non-infectious diseases as pernicious anemia or diabetes, the argument carries little conviction.

The impression of a constitutional defect is

admitted by many observers (Brown¹³, Rosenheim⁶⁵, Friedenwald⁶⁴ and Zweig⁶⁶). Unfortunately in discussing constitution there are no objective, measurable or demonstrable characteristics to indicate the defect in question. What one usually does is to refer as Draper does, to some measurable characteristic, such for example, as the gonial angle which is assumed to be a constitutional characteristic. Then if there is a correspondence between this characteristic and the disease in question the disease will also be assumed to be constitutional in nature. However there is no reason to suppose that there is any degree of parallelism in the incidence of a larger number of constitutional characteristics. Although the question of constitution remains one of impression unsupported by well-defined evidence, it is perhaps significant that there is a widespread impression of constitutional disorder as a basis for the diseases in question.

The most frequently described aspect of these colon diseases is the manifestation of nervous disorder. It is sometimes pointed out that anyone suffering from attacks of exhausting diarrhea might be entitled to some nervousness, but the nature of the disorder is something quite different from what one sees in tuberculous colitis, for example. It appears to be much more a characteristic of the patient's personality than a by-product of some disease process. "Nervousness" is, of course, accepted as one of the most striking manifestations of mucous colitis^{22, 11, 6, 12, 13}. Eggleston²¹, Hunter³⁰, Drueck¹⁵, Jordan³⁴, Barker⁶ and Sherman⁶⁸ have all commented on the neurotic character of patients suffering from spastic colon. While Eggleston²¹ and Hunter³⁰ point out that the symptoms are most frequently incidental to some emotional disturbance. Likewise Bastedo⁷ comments on the exacerbation of mucous colitis by strain and fatigue. This feature is no less striking for ulcerative colitis. Rosenheim comments on the signs of an inferior vegetative system in these patients and Zweig mentions their labile nervous system. Even Larson⁴⁶ and also Bergen^{3, 4}, while holding to the infectious nature of ulcerative colitis point to the importance of psychic factors in bringing about relapses. Murray⁵⁵ and later Sullivan and Chandler⁷² have given detailed personality studies of a number of patients showing how closely related attacks are to emotional difficulties. Murray⁵⁵ believes there is a common psychologic make-up in cases of gastric ulcer and colitis characterized by fearfulness, and points to the emotional immaturity of patients suffering from colitis.

ORGANIC DRIVENNESS

A BRAIN-STEM SYNDROME AND AN EXPERIENCE*

With Case Reports

BY EUGEN KAHN, M.D.,† AND LOUIS H. COHEN, M.D.†

IT is a truism that the make-up of the personality is founded on the biological structure and function of the individual, and that certain aspects of the personality are related to specific structure and function of the nervous system. In support of this truism is our present-day knowledge of brain localization. This point of view has frequently been misinterpreted in that even the most accurate localization of brain functions does not suffice for satisfactory explanation of the individual as a whole. This, however, seems to be a fair statement that the over- as well as the under-development of certain brain areas serves as a sort of background of cer-

tain plus and minus members of the species or, in other words, of certain superior and deficient types. More specifically, the significance of the frontal lobes and of the brain-stem¹ seems to us most important in this connection. It is the brain-stem alone with which we are concerned in this presentation.

We are of the opinion that there exist personality types which owe their existence, at least partially, to a special organization of the brain-stem.² The clinical and pathological investigations of Economo's disease have enriched tremendously our knowledge of this brain area. Years ago Hauptmann³ indicated how change in the brain-stem produced by encephalitis epidemica was effective in influencing the entire personality. Our present observations, not restricted to encephalitis epidemica, have led us to infer the existence of a condition quite the opposite of that which Hauptmann described.

2 One such type has been analyzed by Bostroem, A. Über eine eigentümlichen Form psychischer Entwicklungshemmung mit Beziehung zur Athetose oder zur frühkindlichen Motorik. Arch f Psychiat 75 1 20 1925

He has shown that as a consequence of the degenerative process in the brain-stem his patients developed a "lack of inner impulsion" obviously a clear-cut deficiency of personality function. We have observed as many investigators have done before us that there sometimes develops a surplus of inner impulsion in such patients. This we call *organic drivenness*⁴. We do not maintain that this *organic drivenness* is found in encephalitic and metencephalitic patients only. Rather we conjecture that there may be organically driven individuals who although defective in brain-stem organization do not betray any other evidence of it except *organic drivenness*. Furthermore we surmise that quite a few individuals who are now labelled psychopathic personalities may really be "brain-stem" cases in the widest sense of this concept. On the other hand we feel it necessary to proceed very cautiously with such an hypothesis and to present material where indubitable neurological evidence in addition to the *organic drivenness* guarantee that such personality alterations congenital or acquired, may be related to this circumscribed area⁵.

1 C G Scotch Irish, male, aged 8. His father is an alcoholic, his maternal grandfather had died at 35 of brain tumor. The patient was a term child, an instrumental delivery (birth weight 9 pounds). There was no history of birth trauma. Teething walking and talking occurred at average ages. He had mild whooping cough at four months. At three years of age he had a severe attack of measles and some time later had another attack which was also diagnosed as measles. He entered kindergarten at four and the following year was promoted to the first grade. He then became a disciplinary problem he could not be kept in his seat, and was a disturbing influence on the other children. He read well, far in advance of his age, was good in arithmetic, but could not be induced to write. He remained in the first grade the following year but was dismissed because he frequently left the school at recess time and did not return. He ran away frequently from home as well as from school, and began to steal rides on the trolley cars and trains. He stole money from home and spent it for candy and toys which he would give away to his friends. In 1931 he developed a spasm of the eyes and neck twitches and other 'nervous characteristics'. He began to defecate in his trousers and to smear the feces about. It had always been necessary for his mother to dress him because he could not learn to put on his shoes and to do his buttons up properly.

This small well nourished boy was decidedly restless and even when told to sit still continually moved his legs and his arms making choreiform movements with his fingers. It was difficult for him to keep his eyes closed when asked to do so. He

showed a ticlike movement of his neck in which his head was jerkily thrown back, his shoulders moved rather peculiarly. His gait was definitely clumsy and the left arm swung through a wider excursion than the right. His face seemed rather immobile and there was a slight internal strabismus of the left eye. Testes were undescended. Urinalysis blood count and blood Kahn were negative.

He was always unkempt and his shirt and trousers were rarely buttoned. He talked continuously sometimes to himself or to the task in hand, and frequently whistled. He would always become very much interested in what others were doing but it was impossible for him to do any work independently. He was always ready to do new things but would quit very quickly. The right hand was preferred more often than the left. Handwriting was extremely poor for his age. He cried very easily and frequently complained that his hands and arms felt tired. Psychological examination indicated an IQ of 82 with the report that there were unpredictable oddities in executing commissions, a marked degree of visual motor incoordination and distractibility of attention.

2 A A, Italian male aged 11. He is the sixth of seven children of whom four are feeble-minded and two in the State Reformatory for 'incurability'. The father is said to be an impulsive unreasonable probably brutal individual. The patient was born three months prematurely and at birth weighed four and one-half pounds. He entered school at six and one-half and had to repeat the second grade. He is thought to have practised mutual masturbation at 6 and is known to have been masturbating during the past two years. He has 'always' been clumsy and rather 'poorly coordinated'. School difficulties began in the third grade. He became very restless and overactive did not keep still or concentrate and had periods of excitement when he annoyed and attacked other children without provocation. He required constant supervision to prevent exhibition of his genitalia before girls in the schoolroom, he masturbated quite openly and stole the belongings of others. He frequently was seen to stumble.

The patient was underdeveloped but fairly well nourished. He was generally rather hirsute. He had poor general coordination inasmuch as his gait and the movements of his hands were clumsy. His head projected forward slightly. He was left handed. General muscular tone was somewhat increased. His head was small and bullet-shaped and there was bilateral cryptorchism. Blood count urinalysis blood Kahn, and spinal fluid Wassermann were negative.

He was a steady talker and would become immediately interested in new material. Although he was at first friendly and cooperative he soon became quite excitable and antagonistic, and later became extremely offensive quarreling with those with whom he had been most friendly and accusing others of swearing at him and striking him. He was quite combative, would frequently interfere in the activities of others and would shift the blame to them. Whenever thwarted in any of his meddling activities he flew into tantrums of rage kicking biting or scratching anyone who happened to be in his way, and damaging furniture. He was a consistent liar. There would be interludes of a day or two during which he was more quiet and tractable. His IQ was 82.

3 M J, American, female. The patient is a married childless woman in the forties, a very friendly and sociable person of about average intelligence. She never sits still, she is continually changing the

4 Drivenness is perhaps a rather unusual term which has the linguistic disadvantage of non-existence in the dictionary. We have avoided the use of the word Drive since with our noun Drivenness we wish to imply the extreme surplus of energy which adjectives which might be selected to modify 'Drive' do not seem to describe adequately. The term 'organic' denotes a direct biological source.

5 Lotmar F. In 'Die Stammganglien und die extrapyramidalen Symptome' Berlin 1926 discusses the possibility of a 'Bewegungsmotivzentrum' (center of motor impulsion) in the region of the posterior thalamus, the hypothalamus and the aqueduct.

position of her arms and legs, and twitching may be seen in her face, which is usually smiling, or in her neck and shoulders. Her hands are always moving, now striking her face or neck, now playing with her necklace or wrist watch. The choreiform nature of the movements cannot well be doubted. She can not stop talking. There is always a deluge of questions which one is seldom given time or opportunity to answer. Sentences really rush out of her mouth. If the observer, exhausted by the onslaught of a few minutes' contact, thinks that now she will drink a little coffee, or will pause for something else, he suddenly sees her at the other end of the room arranging a piece of furniture, manipulating a cigarette, talking to someone else, always and apparently unceasingly active.

DISCUSSION

We are not primarily interested in making a label diagnosis in any of these cases. We are aware of the fact that the clinical pictures shown by the children are often seen as sequelae of encephalitis epidemica, they certainly occur also after other encephalitic processes. Mrs. J. may be suffering an incipient stage of Huntington's disease although there is no observable sign of mental deterioration.

In all our cases we immediately observe the following: (1) A high degree of general hyperkinesis with either choreiform or tic like (myoclonic) movements in face, trunk, and extremities⁶, (2) outstanding difficulty, approaching an almost complete inability in maintaining quiet attitudes (be it only for a few seconds), (3) abruptness and clumsiness in the performance of movements, even of relatively simple ones, (4) an explosive motor release of all voluntarily inhibited activity⁷.

We daresay that the symptoms enumerated under 1-4 are related to the brain-stem. The impression that one gets when observing these patients, that here is an "organic" condition, is overwhelming. We realize that every neurologist and psychiatrist is perfectly familiar with these pictures and with the "organic impression" which the metencephalic children especially induce.

The general and special hyperkineses⁸ undoubtedly stands in the foreground of the picture. The patient seems to be a puppet at the mercy of its source, i.e., a defective brain-stem. We assume that the hyperkinesis is the primary symptom and that symptoms 2-4 are secondary aspects of it. It seems to be true that the impulses traveling from the brain-stem are under terrific tension for release and hence put the individual to a greater or less degree out of harmonious motor control. It must be granted that fundamentally the individual is unable to stop such movements since he is unable to prevent their origination in the brain-stem. However, the brain-stem is not the whole individual. By

the use of (or at least in the attempt to use) efferent pathways the individual may resist (or at least try to resist) the impulse. It is readily observed, however, that this resistance, such as in an attempt to sit still, or to control certain movements, does not accomplish very much, for sooner or later control is broken down by the power of the impulse. This may provide some explanation for (2), the difficulty in suppressing the movements concerned for even a short while and for (3), that the stowed impulse finally breaks down resistance abruptly. The clumsiness of the consequent activity indicates the individual's inability to perform movements at his ease and with "gracefulness." The explosive motor release of (4) is probably a special case or extreme of the abruptness and clumsiness (3).

We are aware of the fact that with these last statements we have stepped out of the field of neurological observation and simple description of data and have entered the realm of psychological explanation. This procedure is justifiable since the mere evaluation of neurological symptoms does not furnish sufficient understanding for those ultimately concerned with the personality as a whole. It need scarcely be emphasized that we are never confronted with neurological symptoms alone but rather with individuals under specific biological conditions. To these conditions it is necessary to respond as total personalities, i.e., biologically and psychologically. If any one is put under certain conditions he is bound "to do something about it." The organically driven are no less bound "to do something about it." There are two possibilities with which they must find their way, either they succumb completely to their drivenness or they resist by the attempt to modify what is going on within them.

Concretely, one may recall the horrible and pitiful sight of some of the hyperkinetic patients who, in the acute state of Economo's disease, literally rolled themselves to death. They represented the picture of *organic drivenness* at its extreme. There was no way out of this torture. One could only stand by and helplessly watch a hopeless fight. Fortunately, the situation in the patients dealt with here is not quite so hopeless, although in them also may be observed some fight, the fight of the organism against a kind of foreign body, the fight of the personality against something it cannot stop, something which is beyond the grasp of the individual because of its very nature. Simple and dull persons may readily succumb, sometimes indeed having even a little fun with their "jerks", but many, especially the more intelligent and sensitive resent⁹ their affliction and

⁶ We have seen athetoid movements though rarely. In none of our cases was tremor observed.

⁷ It is very instructive to hold the hands of these individuals for some minutes in order to observe the increased strength of motor discharge in other parts of the body.

⁸ General hyperactivity special choreiform movements tic like mannerisms etc.

⁹ The aspect of resentment which A. Adler has put on the account of organ inferiority is probably only a part of the picture. That organ inferiority and overcompensation do play a certain rôle will be mentioned in a different connection.

fight These individuals try to suppress some of the movements and in this attempt to conceal¹⁰ them from their fellow-men, superpose upon them all sorts of "voluntary" movements calculated to demonstrate the nonchalance of their motor activity (cf Mrs J)

Terms such as "resenting" or "fighting" descriptive of a certain attitude of the individual, imply that there exists in him something more embracing than a mere psychological or biopsychological "reaction" Most comprehensively, this something is quite generally considered *experience* or *experiencing* and however much certain factors (biological or psychological) may actually or apparently on occasion become more significant, it is always the personality as a whole which enters into experiencing It is by the knowledge, appreciation, insight into and evaluation of a given individual's experiences, and his ways of experiencing, that one becomes able to develop true psychological understanding of him. There are two principal ways of examining a given individual's experiences (1) we may observe his expressions¹¹, i.e. the ways and means by which he conveys what is going on within him to the outer world (as by language, mimicry, gesture,—"*Ausdrucks*" psychology), (2) we may ask the person to tell us about his experiences (introspective psychology) There is no doubt that in each of these alternatives a tremendous amount of error on the part of the observer as well as of the observed creeps in, in the observation and interpretation of the tenuous and scanty data at hand In the following discussion we make use of both ways of examination, which is of course, not without the danger of such a combined methodological approach

If, in a clinical situation, we examine the knee-jerks of an individual we are dealing with a neurological sign If, in another situation, we see an individual's face become radiant we interpret this sign as an expression of joy, i.e., the expression of an experience The person whose knee-jerks we test may experience them, probably as a peculiar movement, but certainly one over which he has limited control In the radiant face of the joyous individual a twitch or a tic may be observed (perhaps simultaneously with the radiance) which we do not accept as an expression but rather as a neurological sign It may happen that our radiant individual is conscious of, or experiences the twitch and attempts to conceal it Furthermore, it may happen that with recognition of the onset of the twitch he smiles or grins in order to mask it With these rather simple illustrations we are thrown into the midst of the complex neurological-psychological or bet-

ter, the biological-experiential problem of the *organically driven* patient.

If we observe the hyperkinesis of an *organically driven* person we are not only impressed by a neurological sign but necessarily also we see an individual in whom this sign is biologically produced and who is somehow experiencing it The hyperkinesis appears to be imbedded, as it were, in some experiential make-up In this experience or experiential make-up the whole personality is involved, and upon the individual's way of experiencing will depend what is done or what will be attempted with the hyperkinesis (1) he may let the hyperkinesis have its course, standing by, so to speak, resentfully or resignedly, angrily or irritably, (2) he may energetically try to suppress it, (3) he may carefully superpose upon it voluntary movements What we are able to observe of the individual's experience of hyperkinesis however, are only his expressions, namely (1) the resentment, resignation anger, or irritability, (2) a remarkable exercise of will power and, perhaps with this (3) a more or less pronounced adroitness, respectively It is frequently difficult to see these experiential expressions in their true light Sometimes, too, it is almost impossible to recognize that behind them something fundamental to the experience is going on, which, in our special instance, is a biological (really a pathobiological) function, a neurological symptom, the hyperkinesis

This, however, does not tell the whole story The individuals concerned experience not only the hyperkinesis, but also, and perhaps more intensely, the surplus of impulsion by which the hyperkinesis is brought about In other words, they experience their *organic drivenness* In the experience of their drivenness they may feel themselves more or less helpless and be forced to submit in some way We venture to suggest that not infrequently the relative significance of the experience of the hyperkinesis recedes into the background, individuals may become accustomed to it to a considerable extent and may even become able to automatize eventually some of their attempts of suppression, concealment, and superposition of these movements The experience of the *organic drivenness* itself, however, apparently can never be entirely "forgotten" since it is set loose continuously, via the motor system, against the whole personality These individuals feel themselves, at various times and to various degrees, it is true, literally driven, they cannot stop even if they want to, they are carried away by their *organic drivenness* and have a difficult task to keep pace experientially with it.

From this standpoint we may find some interpretation of the distractibility, general hyperactivity, apparent tachythymic or even hypomanic conduct, the ofttimes startlingly widespread and multifarious interests and special ac-

10. cf. Guttman, E. Beobachtungen bei Chorea minor. *Ztschr. f. d. ges. Neurol. u. Psychiat.* 107 584 617 1927

11. Expression includes what is generally designated as behavior but is more than behavioral reaction because of its experiential source.

tivities which characterize these individuals psychiatrically

The distractability appears as an extreme fluctuation of attention or lack of continued concentration. Explanation of this may be that the individual, always on the verge of another flare-up of his drivenness, is incessantly torn away from his present task. This may often be seen as so called hypermetamorphosis (Wernicke) in a very impressive way. In this, as in all cases, the total make-up of the individual is important in the determination of whether and how far he is driven aimlessly from one useless activity to another, or whether by virtue of favorable temperament and intelligence he is able to give his activities some useful content and goal. In other words it may be possible for the individual to utilize the *organic drivenness* and direct it into adequate channels. The accomplishments of some of the *organically driven* patients may indeed be remarkable. Although they may often display a multitude of diversified interests they somehow possess great ability to integrate them

4 A. R., American, male. Years ago one of us had the opportunity to observe a then 29 year old banker, for a considerable period, and to see him then from time to time. This person was possessed of a very good, if not productive intelligence, was a very kind hearted man, and had numerous friends. He was a stammerer, had quite obvious facial twitchings, and was rather clumsy in his movements. He was never seen to walk, and literally was always "on the run". His activities were stupendous in variety and amount, he was a voracious reader and an exceedingly prolific writer and partook in an almost unbelievably widespread correspondence.

When seen in a group, one felt that it was a terrible strain for him to sit still without talking or moving or occupying himself with something. On every possible occasion he would jump up, burst out with questions or deliver short speeches, smiling and moving.

That such individuals possess a capacity to overcome so severe a biological handicap and to be able to make an asset out of their disability may appear a constitutional paradox. In this connection a careful utilization of the Adlerian concept of overcompensation occasionally may not be amiss.

We have mentioned the two opposite ways in which these patients may deal with their *organic drivenness*. At one extreme are those who, just a prey to their drivenness, live in an aimless way, at the other extreme are those who master their life despite their handicap. Between these extremes many different varieties are found. Among them are those "bad boys" and "bad girls" who after an attack of Economo's disease make their lives and the lives of their families miserable with their "misbehavior". At the mercy of their *organic drivenness* they indulge in all sorts of undesirable conduct and often appear unbearably malicious. That they give vent to, i.e., that they express their *organic drivenness* in their various asocial activities is

frequently not recognized. Sometimes they are filled with resentment but it would be thoroughly erroneous to explain all their behavior as the mere outcome of resentment against their environment.

Among the cases which we were able to see (and we saw quite a few more than are reported in this paper) there were more children than adults. This observation cannot be dismissed as adventitious. The "behavior problems," or better, the specific personality changes, after Economo's disease are generally found in children, whereas in the adult the Parkinsonian pictures are prevalent. It seems plausible to assume that this difference depends largely on differences of the biological reaction of the nervous system toward the encephalitic process in child and adult. We conjecture that a more intensive knowledge of *organic drivenness* will show that the syndrome described is not infrequent in the adult not only because many of the children concerned survive to adulthood, but also because encephalitis epidemica and the other encephalitides are not the only conditions which produce this syndrome. We believe that there are individuals who are possessed of *organic drivenness* from birth, either as the consequence of a prenatal encephalopathy or injury, or of birth injury, or as a constitutional variant.¹²

These considerations lead to the question of whether cases exist in which *organic drivenness* is the only sign of congenital defect in the brainstem. We have not yet seen such a case, in all our patients neurological signs were present which, as has been stated, indicated brain stem involvement. While some of these signs (e.g., twitching) are not very severe the drivenness, on the contrary, seems to influence deeply the personality as a whole, its behavior, and its experiences. There is no doubt that the significance of *organic drivenness* is enormous for the personalities afflicted with it, but we do not believe that it is the only factor by which the whole personality structure can be explained. However profoundly this whole structure may be influenced by it. The *organically driven* individuals whom we had the opportunity to observe were very different as to their intelligence and temperament, and undoubtedly there are considerable differences also in their impulse life. It is the degree and the inter-action of the *organic drivenness* with other aspects of the personality which are ultimately responsible for the whole picture of the individual.

By dealing with *organic drivenness* as a syndrome we wish to emphasize its significance for clinical psychiatry. By this procedure we fall under obligation to discuss two specifically clinical aspects: (1) the disease processes in which this syndrome occurs, and (2) its differential diagnosis.

¹² The investigation of this problem by genealogical methods would be extremely desirable.

(1) We have repeatedly stated that *organic drivenness* is found in encephalitic processes and we conjecture that it may occur in every process which involves the brain-stem, e.g., Huntington's disease and certain cases of general paresis, brain syphilis, arteriosclerosis, and brain tumors. With respect to general paresis may be mentioned some observations made a few years ago with Doctors Bumke and Bostroem in the Munich Neuropsychiatric Clinic. Several paretics with extrapyramidal symptoms were seen and when Dr. Hugo Spatz investigated the necropsy material of these and other paretic brains he was able to demonstrate typical paretic changes in the basal ganglia not only of those cases which had had extrapyramidal symptoms but in quite a few cases which had not presented such symptoms. One may infer from such observations that some conditions of excitement and violent outbursts in the paretics, clinical manifestations of *organic drivenness*¹³, are at least partially, due to the changes in the brain-stem.

One may wonder whether we are overestimating or exaggerating the significance of *organic drivenness* and its relationship to the brain-stem. As a counter-argument one may adduce the extreme hyperactivity which precedes the lack of initiative and hebeticity in the frontal lobe cases of Pick's disease. It is certainly permissible to compare these patients' restlessness and aimless hyperactivity with the *organic drivenness* derived from the brain-stem and from this comparison, surmise that the decrease of frontal cortex control is the primary source of their hyperactivity¹⁴. This conclusion, however, would have to be qualified to state that lack of cortical control may not increase motor discharge directly but does so rather by removal of inhibition of brain-stem activity. Indeed recent investigations (v. Braunnühl)¹⁵ have revealed that in many cases of Pick's disease not only the cerebral cortex but also the basal ganglia are primarily and characteristically involved. We are of the opinion that the syndrome of *organic drivenness* will only be found in individuals in whom the brain-stem is pathologically changed, permanently or episodically.

(2) From the point of view of differential diagnosis the syndrome of *organic drivenness* probably is not, at least at present, of any great importance in the gross organic brain conditions mentioned. It may perhaps eventually be

helpful in the interpretation of some specific symptoms.

There is, however, a large group of clinical conditions in which differential diagnosis is important, and occasionally rather difficult. Some of the relatively mild cases of *organic drivenness* may by virtue of their overactivity impress the observer at first sight as hypomanic, we have encountered this diagnostic confusion. We deem it necessary therefore to point out some differences between *organic drivenness* and temperamental deviations belonging to the group of the tachythymic and the euphoric hypomanic¹⁶.

The tachythymic and the euphoric show a natural vivacity, they are alert and smart. As a group they almost always have a good sense of humor and a ready smile, their smiling is warm and often contagious. Many of them are happy people, and go about in a world which is open to them and which is entirely theirs. Movements are rapid and abruptness and awkwardness are rare. Their movements appear to be clear expressions of their personalities especially of their characteristic temperament, and fall in line with their mood and mood swings.

The hyperactivity of the *organically driven*, on the other hand is never natural, even when they behave "vivaciously" they never seem to be free of restrictions. They lack humor, frequently to a deplorable degree, and their smiling is rather a kind of stereotyped and frozen grinning. They are not happy people even if successful in life and it is hard for them to come to bearable terms with the world and to remain so. Their movements are jerky, hasty, abrupt, clumsy, and attempts to modify them may make them only the more conspicuous. Since these movements are organically conditioned they are not commensurate with their moods and emotions although under stress the hyperkinesis may episodically increase.

These descriptions cover only the relatively clear-cut cases of both types. Combinations may occur in that tachythymics or hypomanics may, if rarely, have ties and the like, in some organically driven individuals there may be a certain temperamental vivacity (tachythymic) or euphoria (hypomanic). Further detailed observations should enable us to differentiate such cases more exactly.

We must mention that occasionally an organically driven patient may appear so odd as to remind us of a "schizoid," usually the differentiation will not be very difficult. It cannot be denied, however, that there exist schizoid psychopaths, with some tie perhaps, who betray a certain amount of *organic drivenness*¹⁷.

13 We may indicate in passing that in some schizophrenic conditions sudden outbursts and the like may also bear some relationship to organic drivenness. One must not, of course, forget the possibility of brain swelling in such cases.

14 A case in which *organic drivenness* doubtless played an important rôle has been published by Bürger H. Zur Frage der "Crampusneurose". Arch. f. Psychiat., 79, 161-169, 1927. He relates the main symptoms to the brain stem and adds that in view of a progressive dementia in this case the cortex is also involved.

15 v. Braunnühl has reported his own investigations and the research done by other investigators in Bumke's Handbuch der Geisteskrankheiten, 11, 633-715, 1930.

16 We refer to some pertinent considerations made by one of us (Dr. Kohn) in Psychopathic Personalities. Yale University Press, 1931, pp. 175-177, 183 et passim.

17 cf. Lange J. Klinisch-genetologisch-anatomischer Beitrag zur Katatonie. Monatsschr. f. Psychiat. und Neurol., 69, 1-49, 1925. In this paper are reported cases of schizophrenia in which organically conditioned motor disturbances related to the basal ganglia were observed. In some of Lange's cases the brain stem changes were verified at necropsy.

SUMMARY

Cases are presented in which hyperkinesia due to surplus of inner impulsion is the predominating feature. This is termed "*organic drivenness*", its association with neurological signs referable to the brain-stem indicates the locus of its genesis in this region. *Organic drivenness* is found in various encephalopathies, notably encephalitis epidemica, but its incidence in various degenerative diseases of the nervous system as well as the probable existence of constitutional types is emphasized. Various differentiating criteria from the hyperactivity of hypomanic and euphoric individuals are discussed. It is in accordance with his personality make-up that the hyperkinesia and the *organic drivenness* are experienced by the individual.

DISCUSSION

DR. HODSKINS This has been a very interesting paper to me, not only because I have seen some of these cases that Dr Kahn describes, but in my work with epileptics this syndrome merges very closely into the epileptic syndrome and the things that epileptics do, the neurological symptoms they manifest, and the things we find in their brain stems at autopsy.

DR. C MACFIE CAMPBELL I wish to endorse what you have said, Mr Chairman, that Professor Kahn's paper has been of extreme interest. It touches a subject that is familiar to all of us, whether working with adults or children, these hyperkinetic individuals with a variety of neurological features. Dr Kahn has emphasized the fact that the organism with focal damage to the part function manifests reactions that can only be explained by the total personality, and that we are apt to concentrate too exclusively upon the focal disturbance of function. A good analysis of a series of organic cases with the separation of those symptoms due to the focal disturbance of function from those symptoms due to the total personality is of great value.

The field that is illuminated by this paper is of wide extent and we are very much indebted to Dr Kahn for the stimulus he has given us.

DR. MYERSON I echo Dr Campbell's words as to the powerful stimulus which Dr Kahn's paper represents. However, my stimulation is in two directions, one of pleasure and agreement, the other of question and rather marked disagreement.

I think that encephalitis has probably illuminated the genesis of the personality more than all the psychological work that has been done. I say this with all due respect to the psychologists who are here present. It is probable that the personality changes are due to lesions of the brain stem and that they are often associated with hyperkinesia, such as athetoid movements, chorea, etc. I think it is also well to emphasize that in general paresis and other organic disease types, the brain stem is as much involved as the cortex. For example, in work done by Dr Raskin and me at the Boston State Hospital, the hypothalamus and the brain stem were more involved than the cortex. Thus far, anyone must be in agreement with Dr Kahn and be grateful to him for calling our attention to the relationship of personality and hyperkinesia to the brain stem.

The difficulty, however, is this in respect to the cases he cites. In the first place, I do not understand that they were in any way related to past encephalitis. In the second place, there was no autopsy work recorded, so that we might have some objective linking up of the hyperkinesia and personality alterations with lesions. I do not see how any theory can lack the objective fact of pathological work and not remain suspended in the air, so to speak. In the third place, we can, I believe, explain as much of these cases by the let go of the cortex as by any brain stem lesions. A good deal of the symptomatology of organic brain disease is due to the release of mechanisms of a lower order by the injury done to centers of a higher order. Thus, when the cortex is injured, one gets twitchings and one might, I suppose, get an excessive drive since the individual might well be at the mercy of every impulse that came his way. Skill is a cortical rather than a brain stem development, and the awkwardness cited by Dr Kahn might well be explained by cortical injury. Even the severe psychoneurosis may show hyperkinesia, twitchings, jerkings, and restlessness comparable to his increase in drive. Some of the cases he describes do not seem to me to have any relationship to brain stem, for example, the banker he cites is a tremendous reader, a tremendous writer, looks after a huge amount of correspondence, and all his driving has a strong intellectual slant which cannot, at the present time, be linked up with the brain stem. Moreover, Dr Kahn assumes a plus set of symptoms, that is, the brain stem is overstimulated. There is hardly a sphere in neurology in which we know anything at all about plus diseases. Almost all the symptoms and syndromes represent deficiency with disturbance of the harmony of functions as a result.

May I say this, too, that the organic drivenness is rather a doubtful term in this connection. Organic drivenness should include a drive toward sex, nutrition, self preservation, since these are the great organic drives.

Let me state that I am grateful to Dr Kahn for his interesting paper. That I am in sharp disagreement with much that he postulates does not lessen my indebtedness.

DR. McPHERSON As I have observed this group of patients, which is familiar to us all, it seems to me there are distinctly two elements concerned, one, with a release of movements, and the other, with the reaction of the individual to that release. The paper is very well written but I have some sympathy with Dr Myerson's feeling that possibly we are allowing the concept to be carried too far if we immediately jump to the conclusion that the entire picture is due to the injury to the brain stem. We know very little of the mechanism by which motor phenomena are released in such injury, but we can explain a great many of the hyperkinetic phenomena as release. It does seem that it is stretching the concept to include all of the reactions as a positive syndrome of the brain stem, as Dr Kahn seems to imply.

DR. EPSTEIN I haven't very much to add to what has already been said except to emphasize that from a purely organic standpoint I think the whole business of hyperactivity is too widespread to be localized in this very small area of the brain stem. I should like to see a good many autopsy reports before I shall be convinced that the trouble lies there.

DR. CORIAT In listening to Dr Kahn's paper and to the various discussions, I am inclined to agree with the discussants. It appears that when one re-

constructs the hyperkinetic phenomena which result from the extrapyramidal lesion, that the extrapyramidal lesion has utilized certain elements of the personality and exaggerated them so that the cases as related may well show certain hypomanic trends or even schizophrenic trends provided that the individual in whom the brain stem lesion had occurred had had these trends in a latent form. This same mechanism of utilizing an organic lesion is also often found in the symptoms of the conversion hysteria. If such an individual had these trends, certain events in the individual's life or even certain emotional disturbances even without brain stem lesion, might have precipitated a typical hypomanic or a schizophrenic psychosis.

DR. HEALY I feel very grateful to Dr Kahn for having given us such a clear presentation. All of us who have worked much with young people have seen individuals of the type which he describes. At present we have under observation a young boy who comes in this category. He seems to have presented this phenomenon of hyperkinesia since birth. As a child of even one month of age he was noted as being excessively restless. He has maintained this characteristic with unvarying trends until the present, when he is nine years of age. Can there be any doubt that there must be something organic in the situation? One cannot help being impressed with the possibility that the pathology originated before birth. As the single member of a family group who presents abnormality he is a most disturbing factor at home, in school life, and elsewhere. His restlessness or drivenness causes him not to be able to conform to any ordinary regulations. For example his inability to sit still at mealtimes and his unwillingness to go to bed at any ordinary hour is most annoying. And yet his tremendous overactivity does not seem to create any fatigue symptoms. As in the cases that Dr Kahn cites this boy is not a typical hypomanic; his urge to activity is on the physical side only—he does not indulge in any flight of ideas.

In regard to the essential pathology in this picture I am inclined to agree with what the other discussants have said and will not reiterate the points which they have made.

To go a step farther with what Dr Kahn has said in relationship to the experience of the driven individual with his own overactivity there is to be added the fact that the social environment plays its part in creating emotional attitudes. For a moment we may take this case I have spoken of. He finds himself at odds with the world. He has been dealt with in all sorts of ways overprotective and severe. Even in the family life it has been difficult to know how to handle him and alternative measures have been used. A circular response is set up: the boy meets the environmental issues with realization that he is an abnormal person, and becomes unhappy and surly. His twitchings and bizarre movements, although not excessive, mark him as a peculiar person easily recognized as such even by his playmates. He proceeds to react, very naturally, with undesirable attitudes which play a prominent part in what we may call his personality characteristics. Thus it is not entirely how the individual looks upon himself that, as Dr Kahn says, forms the picture of his personality trends but also his reactions to perceptions of what others feel toward him.

DR. COHEN It is natural I suppose that my attitude with respect to some of the points raised in the discussion should be defensive. I have had, and have appreciated extremely, the opportunity to watch the concept of organic drivenness grow in

Dr Kahn's mind. There are two general points which I would like to mention if only to reemphasize first, the relationship of encephalopathy to organic drivenness, and secondly the significance of organic drivenness in its purely psychological, that is experiential aspects.

The frequent occurrence of organic drivenness in encephalitis cannot be dismissed as accidental. It is very probable that in many cases in which no history of infection was elicited an unrecognized encephalitic process had at some time existed. On the other hand, it seems plausible to assume that there are many cases in which this is not true and that there is no at least demonstrable, focal pathology. Such cases would argue for a constitutionally conditioned organization of the nervous system in which organic drivenness is the predominant characteristic. Here again the locus of origin of the drivenness in the absence of postmortem material if such were to be enlightening must on the basis of concomitant symptoms and signs be ascribed to the brain stem. In either case encephalopathy is present the question as to whether it is anatomical or physiological is probably only a matter of relative emphasis.

Secondly and perhaps more importantly for psychiatrists are the psychological components of this condition. The organic drivenness is experienced differently by every patient by virtue of the differences in personality make-up of each patient. That such experiencing is aimed toward concealment, or at least socially acceptable disguise of this drivenness is not surprising and indicates as Dr Healy has pointed out, the importance of environmental factors. Furthermore it is probable that it is only in those cases in which experiencing has been changed in the sense that asocial expressions occur that the syndrome and its underlying cause become recognized at all. Here the qualitative difference of organic drivenness from the impulsive outbreaks of schizophrenia and the euphoric excitement of the manic depressive may become clear: the fact that the way of experiencing in each of these states is probably different gives to the surplus of inner drive manifested by each its peculiar quality.

DR. KAHN I am very grateful not only to those who find something acceptable in this concept of organic drivenness but also to those who disagree. I am especially grateful for Dr Merson's remarks which put me under obligation to make some explanations which may not be entirely ripe. I would like to mention that I appreciate the remarks of Dr Hodskins who has seen the picture of organic drivenness in some of his epileptic patients.

Dr Campbell has indicated that infections disease not only encephalitis may bring organic drivenness to the fore. That certainly is the case and I mentioned it only in passing that one must think of permanent as well as episodic changes in the brain stem as they may occur in some infectious disease. Dr Merson's reproach is that we have no autopsy material. Of course we have to admit this but isn't there a huge amount of autopsy material in the literature written since von Economo's first publication? Dr Coriat has said that the hyperkinesia may bring other personality trends into the foreground. I have said and I wish to repeat that the organic drivenness indeed is not the whole personality. We have to find out how the personality experiences this very organic drivenness. That, of course brings up the problem Dr Healy mentioned. We are perfectly aware that the organically driven are living in a world in which they are not only experiencing themselves and this world but

are being experienced by the people living with them. That they encounter all sorts of difficulties goes without saying. That would not, however, fundamentally change our opinions as to this very organic drivenness.

I guess the point at issue is this: Are we entitled to relate this organic drivenness to the brain stem? I think that with caution we are able to do this since, for the time being, we desire to discover diagnostic clues for this organic drivenness. These cases of ours, including the lady and the banker, and I hope Dr. Myerson will take this in good faith, have brain stem symptoms, still, they have cortex and other nervous system structures. They do not experience with their brain stem alone, since they haven't the brain stem alone.

I think I may say what I have in mind with regard to brain localization, begging you to accept this as cautiously as I want to say it, taking nothing for granted, since it is scarcely more than a guess. One may look at the structure or make-up of the personality from various points of view, for example from the point of view of the structure of the nervous system. Let us do this for a moment. There are various areas in the nervous system which may be taken into special consideration, one, the cortex, two, the so-called brain stem, three the so-called vegetative system. I am perfectly sure that all of these areas have something to do with both activity and passivity. I venture to say that the cortex, so far as activity is concerned, seems to be mainly responsible for initiative, that the brain stem is especially concerned with regulation, and that the vegetative system deals mainly with what is quite generally considered vitality. We may assume for the moment that in the case of disturbance of one of these big centers there are two possibilities, a plus and a minus. In the case of cortex involvement we see individuals either with the minus or the plus in the form of under or overactivity as a kind of under or overinitiative so to speak. In the regulat-

ing function of the brain stem, all of us know the minus disturbance. In the vegetative system there is on the minus side a lack of energy, and on the plus side the surplus of vitality. It would be of great interest eventually to exploit the ramifications of these suggestions, especially those concerning the various relationships of the vegetative system. In other words, we commonly see plus and minus disturbances of activity related to the vegetative system. Of course it is perfectly possible that a person possessed of my beloved organic drivenness may also all from some disturbance in the cortex, or have some minus or plus vitality, in such cases we would see, of course, a very complicated picture.

The justification for the concept of organic drivenness is the attempt to isolate one factor, and in this way to restrict the concept as much as possible, it is equally necessary at the same time to broaden the concept in so far as the hyperkinesis is experienced by the personality concerned. So, fundamentally, I cannot feel that I agree with Dr. Myerson.

This leads to the other question Dr. Myerson asked: How about sex? I cannot now give an definite answer. I am unable to tell you of the relation of other centers, per se, I do not think that all sorts of sex experience and behavior are or need be found in these brain stem cases, in these cases of so-called organic drivenness, because, as I wish to repeat, the organic drivenness does not tell the whole story. The organic drivenness is only one conspicuous factor related to the brain stem, a factor which is experienced and, which it has been my purpose this evening to emphasize. At any rate, if we can find out what the organically driven individual is doing, thinking, feeling, experiencing about his organic defects, it may help us a lot it may increase our knowledge of the organic diseases with which we are working. It may offer an interest in the shape of a bio-experiential point of view, which sometimes, at least, seems to recede too much into the background.

MEDICAL PROGRESS

PROGRESS IN DERMATOLOGY

BY HARVEY P. TOWLE, M.D.,* AND JACOB L. GRUND, M.D.*

ALLERGY

THE list of diseases called allergic is steadily growing, as witness Dr. Clarke's paper.¹ No longer does allergy mean only asthma, hay fever, eczema, urticaria and angioneurotic edema. According to Clarke, allergy enters into nearly the whole field of medicine. In his present article, Clarke includes in his list practically all cases of urticaria, angioneurotic edema, seasonal hay fever, most cases of uncomplicated asthma, eczema not due to direct irritation, many cases of rhinitis and recurring bronchitis, most cases of mucous colitis, probably, and some cases of gastro-intestinal symptoms. He also suggests that pylorospasm and gastric and duodenal ulcer may be allergic in origin as well as migraine and Menière's disease. It is a proba-

bility, he says, that certain cases of epilepsy are allergic, and, also, certain cases of arthritis. Evidently, the dermatologist must enlarge his idea of allergy.

Anything which will throw light upon the nature of allergy is of interest to the dermatologist, even though the source of the light is not derived from dermatology itself. Pearson² has investigated the skin reactions of fifty asthmatics and compared the results with the reactions of fifty normal controls. His object, he states, was to determine the immediate dermal response to urinary "proteose" and, in the event of obtaining positive reactions, to correlate them with the dermal responses to peptone, histamine, and protein, and to determine the clinical significance of the observations. He found that,

1. Asthmatic patients tend to give nonspecific skin reactions with solutions of proteins or protein derivatives containing 10 to 20 mg. of nitro

*Towle Harvey P.—Consultant in Dermatology Massachusetts General Hospital. Grund Jacob L.—Assistant Dermatologist Massachusetts Memorial Hospitals. For records and addresses of authors see *This Week's Issue* page 772.

gen per 100 cc In the control group this tendency was much smaller

2 Making due allowance for this tendency, it was found that 38 per cent of the asthmatics gave significant reactions to their own urinary proteose

3 If the asthmatic series is subdivided into two groups, the one composed of patients showing sensitivity to foods or inhalants and the other showing no allergic sensitivity, 50 per cent of the allergic group gave significant reactions to their own urinary proteose as compared with only 15 per cent of the non-allergic group

4 Of the control series only 2 per cent gave significant reaction to their own urinary proteose

5 Solutions of asthmatic proteose produced significant reactions in 32 per cent of the controls Sixteen per cent of these even reacted to a dilution as weak as 1:100,000 It was found that one-half of the latter group had allergic family histories

6 The skin response to histamine was remarkably constant in both normal and asthmatic persons

7 It follows that the skin reactions to proteose are not due to histamine

Pearson concludes that the evidence points to the skin reaction being due to some unidentified toxic substance The possibility that allergic subjects are actually sensitized to such a substance has not been definitely disproved he says

Ernstene and Banks's investigations bear the same relationship to the study of allergy as do Pearson's² in that they deal with allergic diseases pruritus, urticaria and also with the use of histamine which is often used as a pharmacological test of sensitiveness

Six patients with pruritus associated with urticaria were treated with small injections of histamine and so were seven patients with pruritus due to other conditions In three of the six patients with pruritus and urticaria there was relief from the pruritus, and even from the urticaria, but in only one case was the relief lasting It is noteworthy that a repetition of the histamine therapy in the cases of relapse was quite ineffective The patients seemed to have acquired a tolerance for the drug which inhibited a response at all comparable with that obtained in the first course

Of the seven patients with pruritus without urticaria, three were entirely unaffected and four were only partially and temporarily relieved

The writers' conclusion that the results warranted further investigation seems hardly justifiable

Another work bearing on the nature of allergy is that of Werner Jadassohn⁴

In view of the importance that has been attached to the presence of eosinophils in the

wheel as a positive mark of allergy, there is a peculiar significance in the results of Jadassohn's studies He verified Berger and Lang's observations, that eosinophils are extraordinarily numerous in and around the vessels in wheals produced by the application of an antigen He also confirmed their observations regarding eosinophils in the histamine wheal, although he found more perivascular leucocytes than they, perhaps because he used a stronger histamine solution

But Jadassohn went farther He examined, for their eosinophil content wheals (a) mechanically produced in a woman with dermatographism (b) a morphine wheal, (c) an atropin wheal (d) a pilocarpin wheal The result was most interesting No one would consider the wheals from morphine atropin or pilocarpin as allergic reactions, yet the histologic appearances were not to be distinguished from those of so-called allergic wheals There was the same collection of intravascular and perivascular leucocytes most of which were eosinophils Jadassohn regarded the reaction as of purely local origin, not as one depending on a general increase of eosinophils in the blood None of the patients had a blood eosinophilia

It would seem that but one conclusion is possible that, contrary to the general assumption, local eosinophilia in wheals is not the sign manual of allergy

Lester Hollander⁵ reports a case of urticaria due to senna leaves He inquires if it is "an example of an acquired hypersensibilization and is comparable to the experiments of Professor Bruno Bloch"

The case is that of a woman who had taken senna leaves as a laxative for fifteen years without noticeable trouble when suddenly she developed urticaria which gradually increased in intensity When she first consulted Hollander she had hives over the legs for three months, always appearing at night about two hours after going to bed At first the search for the cause was entirely fruitless although it included food tests blood examinations, reviews of her habits, her clothing, and several other things Finally, the definiteness of events attracted his attention and led him to eliminate the senna leaves The result was immediate The urticaria ceased to appear As an experiment the patient was again given senna to chew after she had had no urticaria for two weeks The result was positive The urticaria returned and followed the same course as before

If, as Sontag maintained some twenty or more years ago, scarlet fever is not a disease entity but merely a manifestation of hypersensitization to bacteria in the tonsils we may assume that the symptoms bear some relation to allergic manifestations From this point of view, therefore, von Kostyal's study of the Relations between Acetonemic Vomiting and Scar-

let Fever⁶ bears upon that relationship The question is how

Von Kostyál calls attention to the circumstance that, in scarlet fever, there is nearly always vomiting, and nearly always acetone in the urine Further, it is worthy of note, that, in the affections of which scarlet fever is most prone to be the complication, such as burns, tonsillitis, and postparturition conditions, acetonemia is also present Menstruation, likewise, is accompanied by acetonemia and by impaired liver function Building on this foundation, his argument proceeds Diet, he says, may play an etiological rôle in scarlet fever, particularly if there is present an anaphylaxis to any especial food, for such reaction impairs the liver function and thus renders the organism more susceptible to toxins It might be well, he says, to investigate whether diet can influence the Dick test Von Kostyál thinks that the incidence of concurrence of acetonemic vomiting and tonsillitis is practically the same as that of scarlet fever That, then, is a strong suggestion of a relationship between the two, and is evidenced by the fact that it is possible to arrest acetonemic vomiting by an intravenous injection of convalescent scarlet fever serum

TUBERCULOSIS

The effect upon tuberculous processes of a salt-free diet such as Gerson, Hermannsdorfer and Sauebruch advocated, still engages the attention of some investigators One of the most recent is Bertaccini⁷ who, using animals for the experiment, fed one group with a salt-free diet and a second group with a salt-containing diet To make the experiment more convincing, he gave the second group additional sodium chloride by intravenous injection Both groups were inoculated with bovine and human tubercle bacilli He could not find that the presence or absence of salt made any difference in immunity, as all the animals of both groups contracted tuberculosis, as was proved by autopsy

Bommer⁸ takes a more optimistic view of the inhibiting influence of a salt-free diet upon the activity of the tubercle bacillus He began the dietary treatment at the Giessen Lupus Institute in 1928 and has since treated a large number of cases of skin tuberculosis He cut out common salt entirely, restricted meat, and used vegetables largely as a source of protein supply His diet was generous in fat but poor in carbohydrates An abundance of fresh fruit, vegetables and salads was permitted He reports that under such dietary treatment tuberculous skin foci healed completely, even to the drying up of skin ulcers in three or four weeks Moreover, he found that lupus of the mucosa responded quite as well as lupus of the skin

In some cases, to avoid the unpalatableness of food prepared entirely without salt, he used a

mixture of common salt and other physiologically equilibrated salts, the latter supposedly removing the undesirable toxic effects of the common salt

He explains that the favorable effects of a salt-free diet are due to its action upon the vessel walls by which the disturbed water exchange between the blood vessels and the tissues is restored The diet also restores the cells of the capillary walls to normal function Under the salt-free diet, edema diminishes and venous stasis disappears In support of this argument, he points to the obstinate behavior of children with pasty, cyanotic skins in whom the vascular system is primarily defective, and in whom it is necessary to prolong the dietary treatment unduly in order to obtain an effect upon their tuberculous skin lesions

Eller and Rein⁹ studied the effects of an equilibrated salt diet on two cases of lupus vulgaris, two of lichen planus, four of chronic eczema, and two of acne vulgaris They conducted their experiments by alternately giving the patients, every three or four days, a diet free from salt but with an equilibrated salt of potassium, calcium, and magnesium as a substitute, and a diet containing a measured amount of sodium chloride According to their observations, all cases except those of lupus showed a definite improvement when the equilibrated salt was used and no sodium chloride, and a definite exacerbation when sodium chloride was returned to the diet The failure to influence lupus they attributed to lack of hospitalization and the failure of the patients to carry out dietary directions conscientiously

Ever since Lowenstein announced that he found tubercle bacilli regularly in the circulation in milary tuberculosis, in far-advanced tuberculosis, and in 50 per cent of the cases of rheumatic fever, others have tried to duplicate his findings Haymaker, Ekhardt and Freund¹⁰ report absolute failure in 38 cases investigated, although they followed Lowenstein's technique carefully In neither culture nor guinea pig inoculation were they able to discover tubercle bacilli

Benedek's results¹¹, too, throw doubt on the accuracy of Lowenstein's observations Benedek studied four cases of tuberculosis cutis luposa, 1 of tuberculid, and 2 of lupus erythematosus In each case blood cultures were made according to Lowenstein's method and, as a control, tissue cultures according to the method of C Kiel The tissue cultures were positive for tubercle bacilli in the four cases of lupus, but were negative in the other diseases Once he obtained a positive culture from a case of lupus but later attempts were negative In the one positive blood culture the organisms grew sparsely and in subcultures lost their typical shape and acid-

fast qualities. On the other hand, the organisms in the tissue cultures grew abundantly, both in the original culture and in the subcultures.

The question has been asked, does military tuberculosis attack the skin? Geipel sought the answer. He reports¹² that he found involvement to occur only in nurslings and young children. In children, the point of attack was the subcutaneous tissue in which tubercles developed. In infants and very young children, tubercles were found in the corium and the adjoining epidermis.

Jesionek¹³ starting with the proposition that light baths may have a beneficial or harmful effect upon tuberculous foci in the skin and within the body, gives an interesting dissertation upon the anti-tuberculous function of the skin and the effect of light baths upon it. His experimental studies have indicated to him that the skin actually has an anti-tuberculous function and is the source of the natural defense substances of the organism against the tubercle bacillus. Robert Koch, he says, has called attention to the differences in the reactions exerted by the intradermal and intracutaneous injection of killed tubercle bacilli. Jesionek says that in civilized human beings these natural anti-tuberculous defense substances are deficiently elaborated by the skin because only a small portion of the skin is adequately exposed to the stimuli of light and air. The light and air bath removes this obstacle and frees the skin from the confining influences which reduce its metabolic functions. The first stimulus is provided by the lowered temperature which by the movement of the air and the influence of the light increases pressure and thereby, the perfusion of the skin by way of the parenchyma cells. Jesionek sees in this regulation of the blood supply in the skin the most important biologic effect of the light and air bath. Such perfusion and increase in pressure enable the skin cells to produce anti-tuberculous and tuberculo-lytic substances. But if the true value of the light and air bath is to be obtained it is essential, he says, to avoid light induced inflammation of the skin and, also, undercooling and overheating, for such influences paralyze the parenchymal cells of the skin.

O'Donovan¹⁴ reports a fatal case of sarcoma which developed on a lupus scar after heavy treatment of the lupus with Roentgen rays. Two months before death there were symptoms of internal involvement. The patient complained of weakness, pain below the heart, and of shortness of breath. There was fluid in the right thoracic cavity which contained leucoerythrocytes and endothelial cells. The rays showed secondary deposits in both lungs. In discussing this case, O'Donovan says, that it is recognized that there is a close similarity in the clinical development of oc-

cupational tar carcinomata and of Roentgen carcinomata, that, experimentally, both carcinoma and sarcoma have been produced in animals by the same irritant, hence, as lupus carcinoma has increased in frequency since Roentgen therapy was instituted there is an antecedent probability that sarcoma might develop under similar conditions.

ERYTHEMA NODOSUM AND TUBERCULOSIS

There have been published since the last Progress a number of studies on the relationship of erythema nodosum to tuberculosis. One of the first was that of H. Ernberg¹⁵ who examined 200 cases, most of them in children. Thirty-nine unselected cases were given a particularly thorough consideration. All of them (100%) were found to have demonstrable foci of tuberculous infection chiefly in the pulmonary region. Because of his study of the disease, Ernberg reached the conclusion that erythema nodosum is an autogenous tuberculin reaction of an infected organism and is therefore, in reality a manifestation of tuberculosis. For this reason, all cases of erythema nodosum should be given a careful Roentgen examination and should be treated as cases of tuberculosis. The prognosis is good.

Following Ernberg's lead Dickey¹⁶ made an exhaustive study of 16 cases of erythema nodosum in children under fifteen years of age. The majority of the patients were females. If one considers the intracutaneous test with tuberculin as specific then all in the group were tuberculous, for all were susceptible to intracutaneous injections of artificial tuberculin and to minimal doses of it. In fact four of his cases developed typical attacks of erythema nodosum. Perifocal chest reactions were demonstrated by Roentgen ray examination in the majority of the cases. While earlier students of the disease maintain that the streptococcus is the etiological factor in the disease, Dickey maintains that, when present, erythema nodosum is to be regarded as evidence of an early infection with the tubercle bacillus, or as reinfection unless there is definite evidence to the contrary, notwithstanding the fact that it has been definitely proved that erythema nodosum may occur in children in the absence of allergy to tuberculin and, probably therefore, in the absence of infection. The idea of a streptococcus infection can be sustained in only a very small percentage of cases.

Begg's observations¹⁷ concerned only four children from one to five years of age but are, nevertheless, interesting in that there is a definite history of exposure to infection. The four children had been exposed for five weeks to a patient who died of military tuberculosis eight days before the first case of erythema nodosum developed. All the children reacted positively to the intracutaneous injection of tuberculin and all gave radiographic evidence of a hilar infec-

tion Begg considers these cases to be allergic manifestations of a recent tuberculous infection.

Gordon¹⁸ relates the case of a child of three in whom the development of erythema nodosum seemed to be the precursor of the invasion of the general system by the tubercle bacilli. A week after a lesion of erythema nodosum had appeared a small nodule appeared on the skin. At the same time the sub-maxillary gland was definitely enlarged. Four and one-half months later the nodule on the chin was definitely proved to be a lupus.

Cruise¹⁹ also inclines to the belief that the association of erythema nodosum and tuberculosis is not merely a coincidence. He found that in seven of erythema nodosum a definite diagnosis of tuberculosis could be made, that in four cases it could be strongly suspected, and that in more than one half of his cases their erythema nodosum had developed during or after their connection with an institution devoted to the care of tuberculosis.

Lesné, Boguen and Guillain²⁰ observed a series of 39 patients with erythema nodosum over a period of twelve years. Forty-three per cent of the patients gave a definite family history of tuberculosis. Every case, examined by the Roentgen ray, showed calcareous lesions with hilar involvement in infancy as the primary lesion. All reacted positively to tuberculin. At the end of the twelve-year period twenty-two of the thirty-nine were well, even though some had had a serious extension of their original tuberculosis infection. None had had miliary tuberculosis. None had had tuberculosis meningitis. None had died. Therefore, they concluded that the development of an erythema nodosum in childhood with evidences of tuberculosis indicates a relatively good prognosis concerning the tuberculosis.

LUPUS ERYTHEMATOSUS

Three or four articles have been published during the past year which give particular consideration to the relationship of the disease to tuberculosis.

Thus Pessano²¹ reports that out of 100 cases studied 83 had a tuberculous family history. It is to be noted that he obtained better results in treatment with the bismuth compounds than with the gold salts.

J. M. Lyon²² reports two fatal cases of lupus erythematosus in children which came to autopsy. In neither case was there clinical or pathologic evidence of tuberculosis. Apropos of the fatal issue of these cases, it is noted that the following symptoms of acknowledged import occurred: erythematous cutaneous lesions, rheumatoid pains, hemorrhagic tendencies, high fever, and leucopenia.

Roxburgh²³ reports five fatal cases of which three were autopsied. There was neither evi-

dence nor the history of tuberculosis in any of the cases. Roxburgh says that these fatal cases start from a chronic, localized type, that they are more frequent in women, and that they usually occur between the ages of 20 and 30 years. The presence of arthritis, arthralgia, muscular pains, albuminuria, a purpuric eruption, and a high fever are of bad prognostic significance and suggest the onset of a fatal ending. Death occurs in from one to four months after the beginning of these symptoms and is usually caused by a streptococcal septicemia.

The Paris Correspondent of the *Journal of the American Medical Association*²⁴ has written an explanation of the untoward symptoms and accidents which may accompany the gold therapy. He writes that the harmful effects are due to the action of the drug on the components of the blood, on the endothelium of the capillaries and reticulo-endothelial tissues. The accidents most commonly observed, according to the reporter, are agranulocytosis, purpura hemorrhagica, icterus, nephritis, and aplastic anemia. The variety in the accidents is explained by the selective action of the drug on the various constituents of the blood and blood vascular system. If the toxic effect is exerted chiefly on the red blood corpuscles there occurs a grave anemia, if on the white corpuscles an agranulocytic syndrome. If it affects the blood platelets and the endothelium of the capillaries, the signs are those of purpura hemorrhagica.

IRRADIATION THERAPY

Although much has been published in this field there is little that is new. Therefore in this Review we have included but a few sample papers as illustrations of the type of work which is steadily going on.

Webster²⁵ has treated a number of inflammatory conditions by irradiation. He reports good results in furuncle, carbuncle, whitlow, and erysipelas. The favorable effect, he believes, is due to the destruction of the organisms combined with a reaction akin to inflammation which is manifested by an engorgement of the blood vessels and a diapedesis. Also, the protein shock which is produced by damage to the blood and tissue cells adds its beneficent action.

Van Oettingen²⁶ adds his testimony as to the favorable influence of Roentgen therapy of erysipelas. Sixty-four out of 78 cases treated during the past six years showed an immediate, favorable response to irradiation by a definite lowering of the pulse and the temperature. His method was to give from one-tenth to one-fourth erythema dose applied in such a manner that it included the whole diseased region plus a small margin beyond. If the first treatment had no effect, a second was given which was usually enough to produce visible improvement.

Lenk²⁷ reports the results of an interesting experiment in the treatment of warts by the

Roentgen ray, which is one of the most popular methods in use. "But," he points out, "its results have been almost equaled by the treatment by suggestion." "Could it not be that the favorable results of irradiation should be largely attributed to suggestion?" he asks. He sought the answer by giving simulated treatments of the Roentgen rays avoiding all semblance of verbal suggestion and choosing as subjects for his experiment, cases of juvenile warts because they respond the more readily to Roentgen therapy than the verruca vulgaris. He found that although a considerable number did respond to his simulated treatments nevertheless a majority did better with real exposures than without.

Niles²⁸ undertook an investigation of the question as to whether the Roentgen ray treatment of acne increases scarring. To this end he treated with the rays but one side of the face of forty patients with acne, employing a placebo on the other side. In 57 per cent both sides of the face, the rayed and the not-rayed the scarring cleared equally well. In 5 per cent it was greater on the untreated side and in 3 per cent on the treated. Niles claims that these figures definitely disprove the claim that in acne Roentgen ray predisposes to increased scarring. "The percentage of cures," he says also, "was considerably larger in this series when both sides of the face were irradiated."

Richards²⁹ laments the practice of operating upon cases of external cancer before treating them with the Roentgen rays. Previous treatment by surgery, caustics or electricity so complicates conditions as to make it unnecessarily difficult to accomplish a cure by irradiation. "This is especially true," Richards says, "if the previous treatment has been unsuccessful." In such cases the possibility of completely and permanently healing the lesion is definitely diminished and may even be lost. The radiologists feel that preliminary surgical excision is unnecessary. The results of irradiation are better.

The surgeon performs sympathectomy for disturbances of the vasomotor system. The radiologist attempts to attain the same effect by radiation of the deep sympathetic spinal ganglia. Langeron and Desplats³⁰ employed Roentgen irradiation of the suprarenal and cervical sympathetic regions in 41 cases of vasomotor disturbances of the lower extremities. They employed a 500 Roentgen unit once or twice a week and report good results in Raynaud's disease, acroparesthesia, erythromelalgia, posttraumatic disturbances and trophic disturbances associated with a general sympathetic disturbance. The authors thought that possibly irradiation of the suprarenal region is preferable for the lower extremities and of the region at the level of the first dorsal vertebra for the upper extremities. They think that probably there is little difference between the two and therefore advise treat-

ing them simultaneously. In conclusion they issue a warning that the treatment must be carried on with caution, that, as the aim is to reestablish a disturbed sympathetic equilibrium, one must watch out for an abnormal excitability of the sympathetic and its reactions to the doses given.

Several times in previous reports reference has been made to the discussion which has been going on as to the properties of the Grenz ray and its efficacy in the treatment of diseases of the skin. Muskatblit and Ouspensky³¹ have added to the discussion facts derived from their experiments with the use of the Grenz ray as a fungicide. They are not enthusiastic about the results. Although they administered doses fifty and even seventy times larger than the average single dose they could not succeed in killing the organisms.

LICHEN PLANUS—PSORIASIS

Various theories have been put forth from time to time to explain the etiology of lichen planus. Opinion has seemed to favor the theory of disturbance of the sympathetic system. Now come Jacob and Helmbold³² with a theory of a bacterial origin evolved from their observations on 28 cases. In 25 they isolated on semi-solid dextrose serum agar containing cubes of human tissue a gram-negative anaerobic bacillus. "For successful cultivation of the organism," they say, "the serum used must be inactivated at from 56 to 60 C for a number of hours." They report that the organism was not found in normal skins nor in a number of other papular diseases examined as controls. In a few instances they succeeded by inoculation of the human skin with the bacillus in producing lesions which clinically and histologically conformed to the accepted criteria of lichen planus. The bacillus could easily be demonstrated in the sections in the exudate of the lichen planus lesions after an incubation of forty-eight hours or more.

These findings if confirmed, will upset certain previously entertained ideas concerning the disease. For example how shall we explain the results obtained by such observers as Langeron and Desplats³⁰ noted above?

The findings are also at variance with those recently reported by Jansion and Guillaud-Vallée³³ to the Société Médicale des Hôpitaux de Paris. They reported that they had established through a large number of observations, that "all persons affected with lichen planus or with psoriasis present the reactions of a mycotic allergy."

Thus certainly is a new conception of the etiology of lichen planus. Yet, according to Jansion and Guillaud-Vallée³³, the coexistence of an epidermophytosis and of a trichophytosis is not rare in such patients. They explain the

manifestations of lichen planus on the buccal mucous membrane. So far Jausion has found the tricho-epidermophytic skin reaction positive in every case he has examined, whether the eruption was cutaneous or buccal or both. Nineteen of twenty-one cases are reported as having been cured and two as greatly improved by injections of a polymycotic vaccine.

Jausion and Guillaud-Vallée, moreover, assert that the observations reported concerning lichen planus apply as well to psoriasis in a large majority of cases. He studied 54 cases of psoriasis carefully and obtained the following findings. Thirty-seven (68%) of the psoriatics were at the same time carriers of epidermophytosis or mycotic intertrigos. Forty-four (80%) gave strongly positive reactions to a mycotoxin. Forty-five of the fifty-four cases responded to mycovaccinal treatment. Twenty-nine cases were completely cured by the vaccination alone, without other treatment, although it required from fifty to seventy intramuscular injections to accomplish this. The injections are painless and without general reactions. It is thus shown, the reporters conclude, that psoriasis in these fifty-four patients often manifested itself as a mycosis but more often as an epidermophytid. They admit that other antigens may produce an eruption of psoriasis, such as a streptococcus toxin. Psoriasis, then, is a cutaneous reaction of mycelian origin which explains why it will disappear as a result of not only chemotherapy but also of specific polymycotic vaccine therapy.

May it be that there is a real relationship between the more or less favorable results obtained by the injection of scale extracts reported by various American investigators and these findings reported by Jausion and Guillaud-Vallée³³?

Wong³⁴ now reports a series of ten cases of psoriasis treated by the injection of psoriasis scales. He weighs the scales and to each 10 mg mixes 1 cc of sterile physiologic sodium chloride solution. He reports that five of the ten patients were definitely improved, one being cured. One was slightly improved. Four were not affected.

As opposed to the theories just advanced, Grutz and Burger³⁵ report that their studies indicate that the underlying cause of psoriasis is probably a disturbance of the fat metabolism. They offer two hypothetical explanations. A. That the fats, which are a physiological requirement of the skin, are eliminated through the capillary system in excessively large quantities, and, on entering the epidermis, produce the psoriatic manifestations. B. That possibly non-physiologic or irregularly composed lipoids are the cause. In both instances, they say, the cutaneous manifestations could be considered as an inflammatory reaction to the pathologic supply of lipoids.

"This interpretation of psoriasis," the authors declare, "is supported by the success of a dietary deficient in fats." They have tried it in eleven cases suspending all other treatment during the trial. In four refractory cases it was a complete success. In five cases there was considerable improvement. Two cases are still under treatment, but are showing improvement.

FUNGUS DISEASES

Further experience with 217 cases has convinced van Dyck, Kingsbury, Throne, and Myers³⁶ that trichophytin is of value in differentiating mycotic-like eruptions, provided that it is given regularly and in a concentrate adequate to producing a local reaction. Under such conditions about 30 per cent of cures is obtained. The average number of injections was twelve, given intradermally. They begin with a dose of from 0.1 to 0.2 cc of trichophytin in 1:10 or 1:50 dilution and repeat the injection every four or five days. When the beginning dilution fails to produce a positive reaction within forty-eight hours they increase the strength to 1:10, 1:5, 1:2, 1:1. Rarely do they find it necessary to use the full strength trichophytin. They warn that turbid solutions should never be used under any circumstances as they are bacterially contaminated or contain alcohol used to sterilize the needles.

One of the great problems in the treatment of a fungus disease of the feet has been the sterilization of the shoes. Henderson³⁷ now puts forward a proposition which he says not only sterilizes the shoes but even acts upon the diseased skin. "If," he writes, "a shoe is left for from eight to sixty hours in a closed tin box containing a small dish of formaldehyde the vapor will sterilize the shoe even at room temperature." But apparently it will do even more. Leather, it is said, will absorb a considerable amount of formaldehyde which it will give off again for many hours. So when a shoe, treated with formaldehyde during the night, is worn the next day the formaldehyde vapor given off distinctly influences the skin condition for the better or even, after a time, cures. Furthermore, it protects the feet against reinfection.

For a time thallium acetate enjoyed a certain popularity in the treatment of ringworm of the scalp. The toxicity of the drug was found, however, to be so great that the majority of physicians abandoned its use. Mitchell³⁸, though, retains his enthusiasm after an experience extending over five years. During this period, he reports, he has treated 200 patients varying in age from six months to twelve years. He always examines the urine first as any pathological condition of the kidneys is a positive contraindication of the administration of thallium. Then the child is weighed naked and

the dose calculated on the basis of 85 to 9 milligrams for each kilogram of body weight. A simpler procedure is to multiply the weight pounds by four which gives the dose in milligrams. His final conclusion is that if proper precautions are taken there is no reason why thallium should not be used, especially if the child is under four. If the patient is kept in bed for two days after the administration, toxic symptoms rarely develop, he finds, and if they do appear they are seldom severe and pass off quickly. Thallium should be limited so far as possible, to children under four, and a second and third dose should be given only after a considerable interval.

Finnerud is entirely convinced that the causative factor in *perleche* is a yeast organism, usually a monilia. Goodman²⁹ now takes issue with Finnerud's conclusions. He bases his arguments on the study of two cases, one of chronic *perleche* associated with *erosio interdigitalis blastomycetica* in an adult, and the second an acute case in a child. His conclusion is that the specific organism has not yet been determined. He suggests that the organisms usually found, the staphylococcus, the streptococcus, fungi, and yeasts, are but secondary invaders.

MISCELLANEOUS

*Pink Disease*⁴⁰ is variously known as Swift's disease, erythema arthriticum epidermicum, Haverhill fever, etc., and is more often seen by the pediatrician than by the dermatologist. Braithwaite⁴⁰ gives the cardinal symptoms as erythredema (red swelling), a polymorphic rash followed by desquamation, marked anorexia, muscular hypotonia, mental depression, photophobia, and sweating. The disease occurs in children following or during an acute infection. Its cause according to Braithwaite, is due to an abnormal reaction to daylight. It occurs chiefly among the well-to-do. It is more frequent during the warmer months although it may occur during the winter. Increased blood calcium, erythrocytosis and leucocytosis are common, and an increase in hemoglobin is not infrequent. The cure is to keep the child protected from the daylight.

Every dermatologist has, at one time or another, to use a disinfectant locally. There is, therefore, interest for him in Simmons⁴¹ comparative study of the bactericidal action of iodine and mercurochrome. Simmons treated skin abrasions, superficial incisions, and deep incisions, contaminated with undiluted broth cultures of either *Staphylococcus aureus* or *Streptococcus pyogenes* for various periods of time, with solutions of iodine and mercurochrome, respectively.

Tincture of iodine to 151 wounds contaminated with *Staphylococci* gave sterile cultures as follows: abrasions, 83.4 per cent, superficial incisions, 83.1 per cent, deep incisions, 31.2 per

cent. With wounds contaminated with *Streptococci* it gave sterile cultures as follows: abrasions 75 per cent, superficial incisions, 80.9 per cent, deep incisions 82 per cent. Of the 210 contaminated wounds treated with tincture of iodine, the cultures from 156, or 74.2 per cent, were sterile. Mercurochrome used under similar conditions caused very little reduction in the numbers of the viable test organisms and failed to sterilize any of the 210 contaminated wounds.

Infantile Eczema is often considered by the profession at large as merely a skin disease to be dismissed with a trade formula and the remark that he will outgrow it as he gets older. Koch and Schwartz⁴² however, consider the matter more serious. They report that among 103 patients studied there was a mortality rate of 14.5 per cent and a morbidity rate of 43.6 per cent. Of 56 children admitted to the hospital for eczema alone 17.9 per cent died and 33, or 58.9 per cent had complications. They advise that infants having infantile eczema should not be sent to the hospital, but should be cared for either in the home or in a foster home under medical supervision, or the Speedwell technique of Chapin.

Since the writing of the last Report, the emphasis in regard to *Scleroderma* seems to have changed. In the months preceding that report the interest in scleroderma centered in its response to sympathectomy and the other remedial measures instituted for the relief of a vasomotor disturbance. Judging by the paucity of papers on that subject in the months immediately preceding this Report, that interest seems to have faded. Investigators now seem to have turned to other fields of exploration. From among the later reports we have chosen two for notice, because they depart from routine thought and present new viewpoints.

The first has to do with Selve's work with the parathyroid hormone⁴³. Experimenting with nursing rats, 7 to 14 days old, he succeeded, after daily intraperitoneal injections of 5 to 10 units of parathyroid hormones (Gollip) for three or four successive days, in producing changes identical with scleroderma in 20 per cent of the animals.

A stage corresponding to the edematous stage of this disease developed after a second dose and an atrophic stage after fifteen days. From these results he draws the conclusion that scleroderma, and osteitis fibrosa cystica, and Albers-Schoenberg marble disease of bone are all due to an excess of the parathyroid hormone.

The second article to which we call attention is on the treatment of scleroderma by iodine gas. Breitmann⁴⁴ treated three cases by exposing the affected areas, the hands and forearms, to gas formed by heating iodine crystals, applying the treatment at intervals of from three to five days for a period of from one to three months. All three cases were benefited greatly. Breitmann says that the iodine gas treatment also

worked well in such widely different affections as vitiligo, weeping eczema, and furunculosis.

Diabetes, with its disturbance of the sugar metabolism, notoriously favors *pyogenic infections*. Tauber⁴⁵ studied the blood sugar index in over fifteen hundred cases of various kinds of skin disease of which 250 were cases of furunculosis, pyoderma, and ecthyma. One hundred and eighty-nine of the cases of furunculosis did not have a high blood sugar content. From this fact Tauber reasoned that perhaps the susceptibility to pyogenic infection was because the organism did not receive enough carbohydrate and sugar in the diet. Putting this supposition to the test, he gave his patients a daily intravenous injection of 500 cc of 5 per cent dextrose for five successive doses together with liver and a diet rich in carbohydrates. The results were striking. The pain diminished and the infectious process ceased to spread after the second dose, that is, on the second day. Only four cases developed a second furuncle and only one, a third. Tauber is convinced, therefore, that an increased carbohydrate intake is a definite factor in the production of antibodies necessary to resist invasion by pyogenic organisms.

Blood transfusion in dermatologic therapy is not at all unknown, but has rarely been carried out on the same scale as that reported by Scherber⁴⁶. His report is really a summary and an evaluation. In impetigo herpetiformis he found blood transfusion a life saver. In pemphigus vulgaris, it was a valuable adjuvant. Twice it failed in pemphigus vulgaris. In dermatitis multiformis there was merely a temporary improvement, as was the case in pemphigus acutus malignus. In aphthous stomatitis he secured a remission which however was followed by a relapse. He recommends the measure in acute and chronic purpura, but particularly in purpura hemorrhagica. Severe cases of erythema multiforme he finds favorably affected by a combination treatment of blood transfusion and arsenic therapy. In the treatment of arsenphenamine dermatitis and of a gold dermatitis the results are exceptionally favorable. He also recommends blood transfusion in septic erysipelas, in sepsis following furunculosis, in sepsis from gangrene of the mouth, and in gonococcal sepsis.

Prokoptschuk and Baronowsky⁴⁷ report two cases of impetigo herpetiformis. One in a pregnant woman not treated by transfusion was fatal. A second case was in a non-pregnant woman who, under blood transfusion, recovered. In this second case the eruption was extremely painful, spread eccentrically, and was accompanied by a typhoid-like condition and high temperature. The eruption continued to spread. The woman grew weaker and weaker. Finally a transfusion was given of 370 cc of blood. By the third day the temperature had dropped considerably and by the fourth was normal. In several weeks the woman was completely cured.

They think that neither pregnancy nor changes in the generative organs are responsible for impetigo herpetiformis. They believe, rather, that the cause is sepsis. Their reason for this belief comes from the postmortem findings in the first case, particularly upon the changes found in the spleen which were typically those of sepsis.

MILBANK MEMORIAL FUND

40 Wall Street, New York

John A. Kingsbury, Secretary

Wage-earning families who suffered serious loss of income on account of the depression had 39 per cent more babies in the period of 1929-1932 than their neighbors whose incomes were not reduced following 1929. At the same time there was 50 per cent more illness in families whose incomes dropped most sharply than in families who were not seriously affected by the depression.

These findings in a house-to-house canvass of 8,000 families in eight typical cities, just completed by the Milbank Memorial Fund in cooperation with the United States Public Health Service, will be reported in the forthcoming issue of the *Milbank Memorial Fund Quarterly*, by Edgar Svidenstricker, in charge of the foundation's division of public health activities, and G. St. J. Perrott, consultant to the United States Public Health Service. The authors say that so far as they know, the house-to-house investigation regarding occupation, employment, income, births, and ill health in each of the 8,000 families which they directed is the first of its kind ever undertaken.

The study was limited to white families with wage-earners in the skilled, unskilled, or white collar classes, residing in the poorer districts, exclusive of slums in New York (Manhattan), Brooklyn, Syracuse, Baltimore, Birmingham, Pittsburgh, Detroit, and Cleveland. The average income of these families was \$1,700 in 1929; it dropped to \$900 in 1932.

The investigation revealed that families without any employed workers in 1932 had a birth rate during the depression 48 per cent higher than those which had one or more full-time workers in 1932. A special study in four cities showed that the families living on relief funds had a birth rate 53 per cent higher than those not on relief but with incomes of less than \$1,200 a year.

The average annual birth rate during 1929-1932

per thousand married women aged 15-44 years in the whole number of families studied was 152, as compared with 126 for the nation as a whole. For the families included in this investigation the birth rate was 39 per cent higher where the income dropped than where it did not change. The birth rate for families with incomes averaging below \$1,200 was one and one-half times that of those averaging above \$2,500 but still in the wage-earning class. The highest birth rate, 178 per thousand, states the report, was in families classed as poor in 1929 as well as in 1932. However, it is considered significant that families forced to shift from a higher to a lower income level were found to have a higher birth rate during the depression years than those families who were able to remain in the class from which the downward shift was made. Where the drop was from \$2,000 or more to less than \$1,200 the differential rates were 107 for those who kept their income and 133 for those who suffered a loss. For the drop from those averaging between \$1,200 and \$2,000 to a level below \$1,200 the differential rates were similarly 113 and 157.

The report further states that "the illness rate was relatively great in families without employed workers, less in families with part-time workers only and still less in families with full-time workers." However, these figures do not mean that illness was a cause of unemployment, since the questions regarding health referred only to a period of three months in the late spring of 1933. "In fact," say the authors, ill health as a cause of unemployment was relatively unimportant in comparison with lack of work. They conclude that "in so far as illness is an indication the health of persons comprising families seriously affected by the depression is being impaired."

An important scientific feature of the investigation was that the families, whose breadwinners still had their jobs served as a control group "a yardstick for measuring conditions of those who experienced economic reverses."

CASE RECORDS of the MASSACHUSETTS GENERAL HOSPITAL

ANTE MORTEM AND POST MORTEM RECORDS AS USED
IN WEEKLY CLINICAL-PATHOLOGIC EXERCISES

EDITED BY RICHARD C. CABOT, M.D.
F. M. PAINTER, A.B., ASSISTANT EDITOR

CASE 20141

PRESENTATION OF CASE

First admission A twenty-four year old Hebrew teacher entered complaining of swelling of the left side of her face of a day's duration.

The patient had been in fairly good health all her life except for several rather severe colds associated with cough every winter. During the past winter these almost amounted to one continuous cold. Two or three months before entry she had noticed that her ankles were slightly swollen, but she was not particularly disturbed about this. Approximately one month before admission she began to have dull headaches every morning just after awaking. One aspirin tablet gave relief. Three weeks before admission she had another severe cold with nasal discharge and moderate epistaxis. One week before entry her throat became sore and a cough developed. The following day she became very hoarse and lost her voice. During the past week her eyes had been very puffy, especially early in the morning, and the day before admission she vomited shortly after waking. On the morning of admission she awoke with the left side of her face swollen. She visited her physician for the first time, he advised admission to the hospital. She had never noticed any red or bloody urine. For the past few days she had had some slight blurring of vision with specks before her eyes.

Her mother and father were living. Her mother had diabetes and was taking insulin. Two sisters and one brother were living and well. There was no history of heart or kidney disease in the family.

The past history was essentially negative. She had had a tonsillectomy and adenoidectomy at the age of seven and an appendectomy fifteen years before entry. At that time her urine was negative. Her blood pressure was not recorded.

Physical examination showed a well developed and moderately obese young woman lying flat in bed in no apparent distress. She was slightly stuporous. Her skin and mucous membranes were slightly pale. The tongue was smooth. The breath was definitely urinous. There was no hyperpnea. The lungs were clear. The heart was thought to be probably slightly enlarged, but the examination was difficult because of her large breasts. The blood pressure

was 180/120. There was pitting edema of the lower legs to the knees and slight swelling of the eyelids. Examination of the fundi showed blurring of the disks with edema and many hemorrhages. The vessels were moderately thick. One old healed scar was seen.

The temperature was 99°, the pulse 110. The respirations were 22.

Examination of the urine showed a specific gravity of 1.008 and a slight trace of albumin. The sediment showed 20 to 40 white blood cells, 5 to 7 red blood cells and a large number of hyaline and cellular casts. Examination of the blood showed a red cell count of 2,590,000, hemoglobin 50 per cent. The white cell count was 16,900, 80 per cent polymorphonuclears. There was moderate achromia, with slight variation in the shape of the red cells. Examination of the stools was negative. The Hinton test was negative. The non-protein nitrogen was 80 milligrams. A phenolsulphonephthalein test showed no excretion at the end of fifteen minutes and 4 per cent at the end of one hour. The carbon dioxide combining power was 30.3 volumes per cent. The serum protein was 5 per cent.

X-ray examination showed no definite variation from normal in the kidneys. The heart shadow was distinctly abnormal both in size and shape. There was enlargement both to the left and to the right of the midline. The hilus shadows were increased in density and length. All the larger lung markings were prominent. The transverse diameter of the heart measured 14 centimeters, 9 centimeters to the left and 5 to the right. The diameter of the chest measured 24 centimeters.

She was given fluids up to 100 ounces daily and put on a low salt, low protein diet. She slowly but steadily improved. On the ninth day a note was made that her carbon dioxide combining power was up to 36 and that the casts had nearly disappeared from her urine. Her edema gradually disappeared. She remained in the hospital for eleven weeks and was discharged improved. At that time her urine showed a specific gravity of 1.024 with a slight trace of albumin and with only an occasional white blood cell. Her non-protein nitrogen was down to 66 milligrams. Her serum protein was 5.8, the red blood count 2,850,000 and the hemoglobin 55 per cent. A phenolsulphonephthalein test showed only a trace of dye at the end of one hour.

History of interval Shortly after her discharge she began to have rather severe headaches, especially in the early morning, with some vomiting. The swelling of her legs increased a little for the first week or two, then the edema began to involve both the arms and face. She came to the hospital for observation three weeks before her second entry. The non-protein nitrogen at that time was 60 milligrams, the red blood cell count 2,800,000, the hemoglobin 60 per cent. Since discharge she had re-

mained on her own selected diet, but two and a half weeks before admission she was put on a low protein diet. Following this her edema subsided somewhat, but after a time gradually increased. Not long before her second entry the vision of her left eye became blurred and she was unable to read. For three nights before her reentry she was unable to sleep and had a marked distaste for food. The edema increased very rapidly.

Second admission, a month after her previous discharge

Physical examination showed a pale girl with prominent eyes. Her breath was distinctly urinous. Her face was puffy. There was marked blurring of both disks with slight swelling of the left and also a slight amount of exudate in the left macular region. The blood pressure was 200/120. There was a small area of dullness and diminished breath sounds at the right base with a few scattered râles throughout. The abdomen was moderately tender in the lower part and the edge of a slightly tender liver was felt in the epigastrium. There was moderate edema of the legs and sacrum.

Examination of her urine showed a specific gravity of 1.004, a large trace of albumin and occasional red blood cells, white blood cells and casts. Examination of the blood showed a red cell count of 2,500,000 with a hemoglobin of 50 per cent and a white cell count of 14,300, 64 per cent polymorphonuclears. Examination of the stools was negative. The non-protein nitrogen was 97 milligrams, the serum protein 6.9 per cent.

The patient went downhill steadily. Her blood pressure ranged from 250 to 270/150. She vomited several times. On one occasion there was 400 cubic centimeters of vomitus with a 2 plus guaiac. She became very drowsy. Her non-protein nitrogen rose to 200, her carbon dioxide combining power to 22.4. She went into coma, had a general convulsive seizure and died.

DIFFERENTIAL DIAGNOSIS

DR. CHESTER M. JONES. It seems to me that this is a fairly typical story of terminal renal failure and that the diagnosis should be a fairly straightforward one. Which is cart and which is horse, however, in this story is a little difficult to determine.

She has a story of edema going back many months before admission to the hospital, a generalized edema involving the face as well as the extremities, and a story also of continuous infection of the upper respiratory type going back many years.

It is said that her tonsils were taken out. I should like to know why, but I suppose it was because of repeated sore throats. That was not in the summary. We do not know whether she had any severe throat infections prior to the tonsillectomy.

The upper respiratory infections of which we have a history are not quite of the type that one expects to get with a story of glomerular nephritis.

Her urinary symptoms came on rather rapidly and certainly were the presenting picture when she first came into the hospital.

Even at the time of the first admission she was slightly stuporous. She was very pale. There was a urinous breath. At that time the lungs were clear. There was a distinct impression that the heart was enlarged although it could not be measured accurately. There was no elevation of blood pressure. It was perfectly obvious that in addition to a renal element in the picture hypertension was present. Whether that was the result of chronic nephritis or whether it was in the nature of an essential hypertension which had resulted in renal changes would seem to me to be the difficult point at issue.

Even at that time she showed blurring of the disks, although there is no mention of choking of the disks at the first admission. There were many hemorrhages with thickening of the vessels, showing very definite evidence of arteriolar sclerosis.

Her urine on admission showed a specific gravity of 1.008, which is what one would expect to find with long standing glomerular nephritis or with a vascular nephritis that has been persistent for some time. There were casts, both cellular and hyaline. There was only a moderate amount of albumin.

The most striking thing at the first admission is the red blood cell count of 2,590,000. It certainly indicates very serious renal damage of long duration. That in itself would give a very definite idea of the prognosis in her case. Anemia of that degree with a story of short duration would give a very doubtful prognosis.

The leukocytosis of 17,000 at the first admission I do not understand. There was no obvious source of infection found on admission. There was no throat infection. There was a question of recent sinus or antrum. Possibly it was not fully enough described to make it possible for me to account for the leukocytosis. I do not know how to explain it.

The elevation of non-protein nitrogen of course is very high, 80 milligrams.

It is also interesting that when she came in the carbon dioxide combining power was 30 volumes per cent, which indicates a very real mild acidosis which may occur in renal insufficiency due to failure of excretion of organic acids.

There was the lowering in proteins that may occur in chronic nephritis, which is an indication that in any case one should not limit the protein intake as is so frequently done. That her clinical course during the first admission after the protein intake was increased, I think is prob-

ably the proper thing to expect I think we have been too apt to starve our patients as to protein intake because they have nephritis and hypertension I am sure that they feel very much better and we do not influence the course of the disease by giving them a reasonable amount of protein There is no indication that it will increase the hypertension So far as the edema is concerned, it certainly would have been wise to maintain the sodium chloride intake at a moderately low level

X-rays at the first admission bore out the contention that the heart was enlarged, but there is nothing characteristic so far as the report is concerned as to the character of the heart disease The transverse diameter is obviously greater than normal In a seven-foot plate the dimensions that we have are transverse 14 centimeters with an intrathoracic diameter of 24, which shows very definite enlargement but apparently equally to the right and the left, and I think that film shows it on both sides

DR GEORGE W HOLMES I think that the x-ray bears out the clinical evidence and that your interpretation of it is correct, that the heart is definitely enlarged to both the right and the left With the history one would properly interpret that as hypertensive heart with dilatation of the auricles rather than as rheumatic heart

DR JONES Would it indicate that there had been a certain degree of heart involvement for some time, or is it acute?

DR HOLMES It had gone on long enough to produce some hypertrophy of the left ventricle

DR JONES Of course if she has had hypertension for any length of time that would fit in with the x-ray picture?

DR HOLMES Yes

DR JONES She improved with rest and with a more normal diet than she was given at first and she left the hospital clinically better but from the point of view of the laboratory with no improvement whatever Her anemia was practically the same She still had some nitrogen retention and a slight but true acidosis We do not know what the blood pressure was on discharge, but I assume that it did not drop very much

There is one interesting finding on discharge The specific gravity of the urine was 1.024 All the other gravities were low That would seem to indicate more concentrating ability than one would have assumed at first I wonder if she was getting epsom salts That will increase specific gravity quite a bit if there has been much absorption

Her second admission was really a repetition of the first There was no essential change The only additional thing was that she was having more intense headaches I should say that in this type of disease headaches are to be expected rather than not to be expected She did not

however have a true hypertensive crisis with extreme headache, from that going into a comatose condition

The second physical examination brings out a point that I think is rather important to stress a little, and that is that the examination of the fundi shows not only blurring but actual choking of the disks I mention that merely because when I was a house officer and for some years afterward we were taught that one does not get choking in this condition

The blood pressure has gone up between the first and second admissions, so that her initial pressure instead of being 180/120 is 200/120, a little higher certainly, and in addition we have evidence of heart failure because she has slight dullness at the bases, râles, and a large tender liver At present she comes in not only with evidence of renal insufficiency and hypertension but also with a certain amount of acute heart failure which fits even better into this picture of cardiac enlargement and dilatation that Dr Holmes has mentioned

The edema is present at the second admission just as at the first Otherwise I should say that the findings are very little altered The specific gravity of the urine went down to 1.004, which again indicates a great deal of renal dysfunction, and it is worth while noting that on both occasions she failed to excrete any real amount of dye after intravenous phthalein

She comes in again with a white blood cell count that is roughly 14,000 I think that this time it is associated with respiratory infection, because there was enough dullness localized at the right base to suggest that there might be pneumococcus infection as well

She went down steadily The blood pressure rose to 270/150, which I think is what one might expect, and with that her non-protein nitrogen rose to 200 milligrams and the carbon dioxide combining power to 22 volumes per cent,—very marked inability of the kidney to handle the nitrogen or any organic acids or to concentrate the urine properly

I should think that probably a young woman of this age, in spite of a long story of repeated upper respiratory infections, probably had essential hypertension, arteriosclerosis, with vascular nephritis as a result, or as part of the picture I should be less inclined to think that she has a chronic glomerular nephritis as a result of chronic streptococcus hemolyticus infection of the throat If she has that she has very marked vascular disturbance as well The condition I think is one of the characteristic conditions that one finds in essential hypertension with renal failure

DR TRAUB B MALLORY You saw this patient, Dr Smith Have you anything to add?

DR WILLIAM D SMITH I saw her during her first admission but not at the second I felt at that time that with her history of repeated respiratory infections she probably had a chronic

glomerular nephritis, and that the hypertension and the vascular changes of arteriosclerosis were secondary

CLINICAL DIAGNOSES

Chronic glomerular nephritis with edema
Hypertension
Uremia
Hypertensive retinopathy

ANATOMIC DIAGNOSES

Chronic glomerular nephritis
Ascites
Hypertrophy of the heart
Bronchopneumonia
Acute gastritis
Operative wound old, appendectomy

PATHOLOGIC DISCUSSION

DR MALLORY The autopsy here showed only moderate enlargement of the heart. It weighed 350 grams, which would be within normal limits for a large man but is definite hypertrophy for a small girl.

The kidneys weighed 120 grams, were very much shrunken, granular, with a narrow cortex, and microscopically showed a pretty typical glomerular nephritis with well marked capsular adherence and endothelial proliferation within the capillaries.

As is usual in any case of long standing glomerulonephritis with much atrophy of renal substance, there is considerable sclerosis of the renal vessels. This does not look, however, like a very active progressive process such as one would expect with a superimposed vascular nephritis, and the arterioles elsewhere in the body were free from degenerative changes.

There was a terminal bronchopneumonia, as was prophesied.

CASE 20142

PRESENTATION OF CASE

DR PAUL D WHITE This case was one of extraordinary interest to me. The patient was a man of forty-eight whom I saw last August.

Present illness He was referred to me because of severe attacks which I will describe by reading my original notes. He had always been well and very active. He had been under heavy strain for the past two years, mostly associated with the business depression. About five or six weeks before I saw him, while he was on a vacation in New Hampshire, he had an attack of old-fashioned stomach ache following a "hot dog" roast the night before. The pain started in his mid-abdomen, went up into the left chest and lasted all day. It hurt him to breathe, not markedly but somewhat. He drove his own car home nevertheless to Connecticut from the White Mountains. That night at home he saw his doctor, who said he had congestion in the left chest and fever. He spent the next day in bed and after that resumed work.

The chest pain felt like a pleurisy pain, as he called it, and lasted a week, gradually subsiding. He was then quite well again, drove up to the mountains for his wife and came back two days later feeling well. He ate a hearty supper and slept well all that night. While preparing early breakfast himself the next morning he had a catch in his throat, found it hard to breathe and became panicky. His doctor came, gave him morphia and put him to bed. There was a consultation between two local doctors. There was some uncertainty about the status of his heart, and a question of coronary thrombosis was raised at the time. He was then referred to me.

He had been given digitalis at the time of his second attack two weeks before I saw him. He took it in a dosage of fifteen drops twice a day until two days before I saw him, then eight drops a day. He had stayed in bed five days and had been up and feeling fairly well after that and back at work.

Five days before I saw him he was tired and had a little fever. Although he was quiet at work he had been active in other ways. One day he went to a bridge party and to the movies and was quite tired after that but without symptoms of chest pain. He was exhausted the next day and had a spell of palpitation which lasted twenty to thirty minutes. The heart pounded at the time, but he did not note as to whether the rate was fast or not. He had some dyspnea but no gasping.

Past history He had never been ill except for scarlet fever as a boy. His tonsils had been burned out. He had recently lost nine pounds in six weeks, but he was on some restriction of diet just before I saw him. He had for years smoked six to eight pipefuls of tobacco a day. He took no alcohol, and drank coffee moderately. He had been very active, playing tennis, mountain climbing, etc. He was in the habit of taking a strenuous annual vacation in the summer. There was one other point that he told me, that was that he sprained his leg severely nine or ten weeks earlier, four weeks before the attack of stomach ache followed by pain in the left chest in New Hampshire after the "hot dog" roast the night before.

Family history His family history is not remarkable. His mother and one brother were living and well. His father died at sixty-two of arteriosclerosis. He had two adopted children, one of whom was causing him a great deal of nervous anxiety.

Physical examination On physical examination he appeared to be in good general health. His breathing was normal. The reflexes were normal. There was no arcus senilis or thyroid gland enlargement. The teeth were in fair condition. The tonsils were small and reddened. No abnormal pulse was visible in the neck. The heart was at the outer edge of normal in size. The sounds were short but otherwise normal.

There were no murmurs. The heart rhythm was normal. There was no precordial tenderness. The pulse was normal. The artery walls were soft. The lungs were clear. The abdomen was soft. The liver and spleen were not felt. There was no dependent edema or clubbing of the fingers. Pulse rate 96. Blood pressure 165/85. He was nervous at the time.

An electrocardiogram showed sino-auricular tachycardia, rate 120. It was taken when he first came to the office and he was more nervous than later. As a rule we find tachycardia when the electrocardiogram is first taken. There was a slight tendency toward low voltage. That is not remarkable. There were rather low T waves, not strikingly abnormal.

Fluoroscopic examination by myself showed a full sized heart, just at the edge of normal. The measurements were 11.5 centimeters for the transverse diameter of the heart and 23.5 for the internal diameter of the thorax. The heart was active, showed visible pulsation. The lungs were questionably normal. The pulmonary arteries showed slight increase of prominence, but there were not many variations from the normal.

I thought then that he had no serious heart disease, a normal irritable heart, with a question of neurocirculatory asthenia, a question of paroxysmal tachycardia, a question of pulmonary embolism and a question of coronary thrombosis. I thought his prognosis would be good. Seven days later, however, his brother-in-law called me and said the patient had died suddenly that morning. My first thought then was that I certainly had missed serious coronary disease, but a bit later I found that the final illness was one of six or eight hours, consisting of collapse and a state of shock, and then I was not so sure.

Postmortem examination was asked for and at first refused, but at the time one of the doctors who was taking a graduate course with us suggested that if this were pulmonary embolism related to his leg injury in playing tennis it might be considered an accident and therefore might entitle him to more insurance. Therefore I wrote that to the patient's doctor, and the family then agreed to the postmortem examination. The body was exhumed.

CLINICAL DIAGNOSES

Possible coronary disease

Possible recent pleurisy or pulmonary embolism

ANATOMIC DIAGNOSES

Pulmonary embolism

Infarcts of the lung

Hypertrophy of the right heart, slight

PATHOLOGIC DISCUSSION

DR. TRACY B. MALLORY. Dr. Castleman went down to Connecticut to examine this exhumed body and he will tell you what he found.

DR. BENJAMIN CASTLEMAN. The body was in good condition. It was well embalmed.

On opening the chest cavity the heart did not appear very much enlarged. The right heart appeared slightly thicker than normal, measuring 6 millimeters. We did not find anything wrong with the coronary vessels. There was no infarction of the myocardium anywhere.

On examining the lungs we noticed that on the left side there were fairly definite firm areas on the periphery, and when cut into they appeared to be typical infarcts. Although the embalming fluid had caused the whole lung to be fairly firm, these infarcted areas were much firmer, and on cutting deeper we found the pulmonary vessel to this area completely thrombosed. There were two or three infarcts on the left side which were larger and also one which stands out here quite definitely on the right.

We did not have permission to examine the leg which he was said to have sprained, so we do not know whether there were any thrombi there or not. We merely examined the chest.

DR. RICHARD C. CABOT. What do you think the old-fashioned stomach ache was?

DR. WHITE. I suppose that was the point of first location of the pain associated with the pulmonary embolism, the first attack. I believe that all of his attacks were embolic, one after another, and that one finally killed him.

DR. CABOT. Are you accustomed to find pulmonary embolism pains at that point?

DR. WHITE. No, but I think we may find any pain due to disease in the chest start low down in the epigastrium and radiate upward. Such a story is not uncommon in angina pectoris. I do not see many cases of pulmonary embolism and I do not know how often such a distribution of pain may occur in such cases.

A PHYSICIAN. Might the pain have been caused by diaphragmatic pleurisy in this case?

DR. MALLORY. We had recently a case of infarction of a lower lobe of the lung causing diaphragmatic pleurisy with such intense abdominal pain that an exploratory operation was done for acute pancreatitis.

DR. WHITE. And pain in the chest?

DR. MALLORY. Not so far as I can remember.

DR. WHITE. This case was of interest to us because of a study we have been making of a group of cases in which the differential diagnosis between coronary thrombosis and pulmonary embolism has been rather difficult in severe cases of pulmonary embolism with dilatation of the right heart. This patient came along as we were studying some hospital cases. We were not fortunate enough to see him during the acute process, otherwise we might have found some of the signs and symptoms.

A PHYSICIAN. An x-ray film might have been of some assistance.

DR. WHITE. Yes, and possibly an electrocardiogram, but we have not gone far enough yet to be sure.

THE REPORT OF THE SPECIAL INDUSTRIAL DISEASE COMMISSION

THIS commission has operated under Chapter 43, Resolves of 1933 of the Massachusetts Legislature. The report sets forth the findings of the studies conducted by this body covering working conditions in the granite and foundry industries, the effect of their conditions on the health of workers, the means of lessening dust exposure, and the legislative and administrative aspects of the occupational disease problems.

Fifteen granite and foundry establishments were visited and studied where 2100 granite, and 6,700 foundry workers, were employed. The nature of the work in these industries is fully explained in the text of the report, and illustrations and charts convey information which augments that embodied in the text.

As a result of the work done by this commission, a series of recommendations is included in the report which sets forth preventive regulations, various amendments to present laws relating to insurance of workmen, physical examinations of the employees, compensation for dis-

ability, protective regulations, the computation of insurance premiums the creation of a Division of Occupational Hygiene in the Department of Labor and Industries a Division of Adult Hygiene in the Department of Public Health, and a Medical Board of Review, whose duties shall be to review, on request by the Industrial Accident Board, reports and findings of the Department of Public Health furnished with respect to compensation cases and findings of physical fitness made by the Department of Public Health.

This board if the recommendations are adopted, may hold hearings and render decisions.

It is provided in the recommendations that this Medical Board of Review shall be composed of a clinical pathologist, a roentgenologist and a specialist in diseases of the chest, to be paid on a per diem basis.

Drafts of fourteen special acts appear at the end of the report. These are designed to make workable the recommendations of the Special Industrial Disease Commission.

This report is of especial interest to physicians who may be called to care for the granite and foundry workers and should be studied by the Committee on State and National Legislation of the Massachusetts Medical Society, because it includes important health measures and economic problems.

Under the initiation of Dr. Robey, President of the Massachusetts Medical Society, conferences have been held with such persons and groups as have indicated interest in the report.

PRESIDENT ELIOT'S RELATIONS TO MEDICINE

NONE but a comparatively small number of physicians in active life know of the influence exerted on medical education by Charles W. Eliot, except as one may have been interested in the history of his life and his accomplishments in the graduate schools as well as the University. The recital by Dr. Walter B. Cannon in this issue*, of those years of devotion to the Harvard Medical School will be enjoyed by those who knew of the difficulties encountered when the then young president carried through his plans for an improved medical curriculum over the opposition of some of the members of the faculty.

Dr. Eliot was especially concerned in the training of doctors, and repeatedly urged larger classes for the medical school in order to supply a greater number of well-qualified physicians, thereby gradually displacing the irregulars who formerly constituted a large proportion of practitioners throughout the state.

He lived to see medical education largely reconstructed and coördinated with the sciences which play so large a part in dealing with illness.

His interest in medicine was not confined to

the medical school, for on several occasions he responded to appeals for his assistance at hearings before legislative committees when matters of public health were under consideration. On many occasions he was the leading speaker at the annual banquets of the Massachusetts Medical Society, and gave substantial and important advice to the doctors, often with pointed references to their deficiencies.

All who are interested in medical education, and especially President Eliot's relation thereto, may read the oration of Dr. Cannon with profit.

HOUSE BILL 1305

THIS bill was designed to authorize the University of Massachusetts to grant the degree of Bachelor of Science. It passed the House and Senate by a large majority. His Excellency, Governor Joseph B. Ely, vetoed the bill when it was sent to him, and his veto was sustained by roll call vote of 55 to 151 in the House. Webster's dictionary defines University as "An institution organized for teaching and study in the higher branches of learning and empowered to confer degrees in special departments", etc.

This so called University was given a charter by the Commonwealth of Massachusetts, and, by reason of the title given to the University, it has been supposed by some to be a state institution. On the title page of a recent pamphlet the following words appear: "University of Massachusetts Middlesex College of Medicine and Surgery Affiliated."

Frank L. Whipple, A.M., M.D. is recorded in this pamphlet as President of the University and Dean of the Faculty of Medicine. The major purpose of this publication seems to be to set forth the purposes and methods of the Middlesex College of Medicine and Surgery, one of which, on the inside page of the cover, appears to be to provide instruction for "poor but worthy students."

If the power to confer the degree of Bachelor of Science had been given to the University of Massachusetts it would have been construed as an indorsement by the State of Massachusetts, and would have been of advantage to the Medical School.

Governor Ely does not seem to feel that the University of Massachusetts is entitled to an extension of its powers.

MISCELLANY

MAKE MOTHER'S DAY MEAN A BETTER CHANCE FOR MOTHERS EVERYWHERE

An important step forward in the effort to save mothers lives will be taken in 1934 Mother's Day—May 13—is to be observed throughout the country by local groups determined to know precisely what their own maternity facilities are how they can be improved how to improve them

Wherever surveys have been conducted the same conclusion has been drawn—that two-thirds of the women who die die needlessly In various places there may be fractional differences in this percent age, but they are of slight significance

Merely deploring this condition will not change it. Wishing will not change it. An effort every where is needed by parents physicians and nurses *first*, to know precisely the facilities of their own communities and *secondly* to make these facilities measure up to the standards of adequate care Clubs and civic organizations can provide the machinery for coordinating such an effort.

Forms for making local surveys to appraise what exists and suggest improvements are available on application to the Maternity Center Association. Every local club or group sending in a form will receive free a copy of the Maternity Handbook by Anne A. Stevens The three clubs sending in the best appraisals will be sent a complete maternity display equipment, which may be used to teach maternity hygiene to mothers The display includes mother's clothes baby's clothes, toilet trays—everything that is needed.

The contest closes May 1 Awards will be made in time for announcement on Mother's Day

Valuable knowledge has been obtained by studies of maternal facilities in several places in the United States One of the most interesting of these was conducted by the Children's Bureau.

In fifteen states, the Children's Bureau investigated a total of 7,380 deaths from causes connected with maternity Interviews with attendants were conducted by physicians on the staffs of the State Boards of Health or the Children's Bureau In each state the study was made at the request of the State Medical Society The attending physician or midwife was visited as soon as possible after the death and in hospital cases the hospital was visited Among the facts found were these

Nine per cent of the women had received no medical supervision at all or only when dying

Only 54 per cent had any prenatal care whatever, 24 per cent received poor care and only 13 per cent had good care beginning not later than the fifth month

More than half the women had some operative procedure of these 43 per cent were women whom the doctor had not seen before labor or before the acute emergency In 11 per cent of the cases there had been a cesarean section

The rate was higher for urban than for rural sections being 75 per thousand live births and 55 respectively

A study of your own community will disclose facts more specific than these and indicate definitely just what is needed among your own people to help save mothers lives

APPOINTMENTS IN THE FACULTY OF BOSTON UNIVERSITY MEDICAL SCHOOL

Dr Winfred Overholser Assistant Commissioner of Mental Diseases in Massachusetts and president of the Massachusetts Psychiatric Society has been appointed to the position of Professor of Psychiatry in the Medical School of Boston University

Dr Louis G. Howard has been advanced to the position of Professor of Orthopaedic and Fracture Surgery and Dr Rudolph Jacoby to Professor of Dermatology and Syphilology

Dr Otto J. Hermann, Boston, has been appointed Associate Professor of Orthopaedic and Fracture Surgery

The list of assistants includes Dr Phillips Boyd Boston in Surgery Dr Bert B. Hershenson Brookline Gynaecology Dr Anna M. Allen Boston Neuropathology Dr Jose P. Bill, Wayland Public Health Dr Ralph M. Chambers, Taunton Clinical Psychiatry Dr I. William Freeman Worcester Pathology and Dr Joseph M. Hussey Wollaston, Pathology

Dr Charles Bradford of Boston has been appointed Fellow in Surgery

the medical school, for on several occasions he responded to appeals for his assistance at hearings before legislative committees when matters of public health were under consideration. On many occasions he was the leading speaker at the annual banquets of the Massachusetts Medical Society, and gave substantial and important advice to the doctors, often with pointed references to their deficiencies.

All who are interested in medical education, and especially President Eliot's relation thereto, may read the oration of Dr. Cannon with profit.

HOUSE BILL 1305

THIS bill was designed to authorize the University of Massachusetts to grant the degree of Bachelor of Science. It passed the House and Senate by a large majority. His Excellency, Governor Joseph B. Ely, vetoed the bill when it was sent to him, and his veto was sustained by roll call vote of 55 to 151 in the House. Webster's dictionary defines University as "An institution organized for teaching and study in the higher branches of learning and empowered to confer degrees in special departments", etc.

This so-called University was given a charter by the Commonwealth of Massachusetts, and, by reason of the title given to the University, it has been supposed by some to be a state institution. On the title page of a recent pamphlet the following words appear: "University of Massachusetts Middlesex College of Medicine and Surgery Affiliated."

Frank L. Whipple, A.M., M.D., is recorded in this pamphlet as President of the University and Dean of the Faculty of Medicine. The major purpose of this publication seems to be to set forth the purposes and methods of the Middlesex College of Medicine and Surgery, one of which, on the inside page of the cover, appears to be to provide instruction for "poor but worthy students."

If the power to confer the degree of Bachelor of Science had been given to the University of Massachusetts it would have been construed as an indorsement by the State of Massachusetts, and would have been of advantage to the Medical School.

Governor Ely does not seem to feel that the University of Massachusetts is entitled to an extension of its powers.

THIS WEEK'S ISSUE

DAMESHEK, WILLIAM M.D. Harvard University Medical School 1923. Associate Physician, Beth Israel Hospital. Physician, Boston Dispensary. Physician to the Blood Clinics of the Beth Israel Hospital and Boston Dispensary. Physician, Research Division, Boston State Hos-

pital. Instructor in Medicine, Tufts College Medical School. Address 371 Commonwealth Avenue, Boston, Massachusetts. Associated with him is

BERLIN, DAVID D. M.D. Tufts College Medical School 1923. F.A.C.S. Surgeon to Thyroid Clinic, Beth Israel Hospital. Assistant to Visiting Surgeons, Boston City Hospital. Assistant Professor of Anatomy, Tufts College Medical School. Address 68 Bay State Road, Boston, Massachusetts. And

BLUMGART, HERRMAN L. B.S., M.D. Harvard University Medical School 1921. Visiting Physician, Beth Israel Hospital. Associate Professor of Medicine, Harvard University Medical School. Director of Medical Research, Beth Israel Hospital. Address 330 Brookline Avenue, Boston, Massachusetts. Their subject is "Complete Ablation of the Thyroid Gland in a Case of Chronic Lymphatic Leukemia with Hypermetabolism." Page 723.

CANNON, WALTER B. A.M., S.D., LL.D., M.D. Harvard University Medical School 1900. George Higginson Professor of Physiology, Harvard University Medical School. His subject is "President Eliot's Relations to Medicine." Page 730. Address Harvard University Medical School, Boston, Massachusetts.

WARREN, SHIELDS A.B., M.D. Harvard University Medical School 1923. Pathologist, New England Deaconess, Huntington Memorial, Pondville State, New England Baptist and Robert B. Brigham Hospitals. Consulting Pathologist, House of the Good Samaritan. Director, State Tumor Diagnosis Service. Instructor in Pathology, Harvard Medical School. Address 195 Pilgrim Road, Boston, Massachusetts. Associated with him is

CANAVAN, MYRTLE M. M.D. Woman's Medical College of Pennsylvania 1905. Formerly Pathologist, Department of Mental Diseases. Curator, Warren Anatomical Museum, Harvard University Medical School. Address 25 Shattuck Street, Boston, Massachusetts. Their subject is "Frequency of Cancer in the Insane." Page 739.

EVANS, WILLIAM A. JR. A.B., M.D. Johns Hopkins University School of Medicine 1930. House Officer, Peter Bent Brigham Hospital. Voluntary Assistant Medical Clinic, University of Wurzburg. Research Fellow in Medicine, Harvard University Medical School. His subject is "The Common Nature of Peptic Ulcer and Colitis." Page 743. Address 460 Vanderbilt Hall, Harvard Medical School, Boston, Massachusetts.

KAHN, EUGEN M.D. Universität München Medizinische Fakultät, Munich, Bavaria 1911. Professor of Psychiatry, Yale University School

RECENT DEATHS

MAHONEY—STEPHEN ANDREW MAHONEY, SR. M.D., of 628 Dwight Street, Holyoke, Massachusetts, with an office at 630 Dwight Street, died at his home, March 30, 1934 of a heart attack.

He was born in North Brookfield in 1863 the son of Jeremiah and Mary A. (Healey) Mahoney. His premedical education was acquired in the public schools of Gloucester and Holy Cross College where he was given the degree of Bachelor of Arts. His medical degree was conferred by the Harvard Medical School in 1889. After an internship at the Boston City Hospital he began practice in Holyoke and in 1892 he was appointed city physician and a member of the board of health survey until 1894.

After a few years of general practice he devoted his major interest to surgery, and in later years restricted his work to this specialty.

Dr. Mahoney was surgeon on the staffs of the Holyoke City and the Providence Hospitals.

He joined the Massachusetts Medical Society in 1888, was a member of the Council for many years, and was a Fellow of the American Medical Association. He was a member of the New England Surgical Society. His interest in civic organizations was marked by devotion to the affairs of Holyoke as shown by the positions of bank president and president of a municipally owned railroad.

He is survived by his widow, Mrs. Caroline L. (Munn) Mahoney, two sons, Stephen A. Mahoney Jr., who was associated with his father, Dr. Edwin M. Mahoney, now associated with the staff of Bellevue Hospital New York City, one daughter, Mrs. Charles R. O'Neill of Holyoke and a sister, Katherine A. Mahoney, principal of the Kirtland School.

MAHONEY—EDWARD JOSEPH MAHONEY, M.D. of 73 Chestnut Street, Springfield Massachusetts died in that city, March 26, 1934, after a long illness following a sunstroke six years ago suffered while playing golf in Nassau Bahamas.

He was born in Holyoke on January 22 1869 the son of William and Catherine (Kelley) Mahoney. He was educated in the schools of his native city, graduating from the High School. In 1892 he received his A.B. degree from Holy Cross College, his M.A. degree from Georgetown in 1893 and his M.D. degree from Georgetown University School of Medicine in 1895. His record in the several educational institutions was exceptionally high, and was recognized by Holy Cross by the award of the Flatley Gold Medal for his work in rational philosophy.

After leaving Georgetown he spent two years in the study of medicine in Europe and returned to Holyoke to practice medicine in 1897. He moved to Springfield in 1910 and was given the position of head of the reorganized staff at Mercy Hospital. Dr. Mahoney was appointed Medical Examiner in April 1914 for the Springfield district, but resigned this office after about five years because of the de-

mands of a large practice. He joined the Massachusetts Medical Society and was a member of the American College of Surgeons, the New England Surgical Society, and the Springfield Academy of Medicine. He was a Fellow of the American Medical Association until he gave up active practice. He was a member of social and civic organizations.

He is survived by a brother, Patrick Mahoney, and several nieces and nephews.

HILL — ERNEST L. HILL, M.D. of Framingham, died on April 1 at his home at the age of 56. Born in Athol he attended the schools of that town and Concord New Hampshire. He was graduated from Dartmouth College and from Dartmouth Medical School in 1902.

After a service at the Boston City Hospital he practiced in Millis for sixteen years removing to Framingham fifteen years ago.

Dr. Hill was a member of the Alpha lodge of Masons and the Framingham lodge of Elks. He is survived by his widow, his mother, a son and a daughter.

NOTICES

TO ALL PERSONS INTERESTED IN THE PAYMENT OF VOUCHERS FOR MEDICAL SERVICES RENDERED TO INJURED CIVIL WORKS ADMINISTRATION EMPLOYEES

A certain amount of delay in the settlement of vouchers for medical services rendered injured employees of the Civil Works Administration is unavoidable. Legislation extending compensation benefits to these employees was not approved until February 15 1934, and the Commission has had to engage personnel and set up its organization to handle the large volume of additional work which is involved in the settlement of claims arising out of Civil Works employment.

Before approving vouchers for medical services it is necessary for the Commission to have received from the local Civil Works Administrators complete reports relating to the injury of the employee concerned. Since the entire work program was organized very quickly, some localities were slow in setting up the necessary local administration to take care of injury reports and due to unfamiliarity of the personnel with the requirements and procedure many reports of injury have been incorrectly filed, necessitating correspondence to obtain the information which was lacking.

In view of the problem presented, the Commission bespeaks the patience of physicians and others who have bills for medical services pending. Every possible effort is being made by the Commission to speed up the work of examining and certifying these claims for payment, and it is believed that within a short time considerable progress will be made in further expediting these payments.

U S EMPLOYEES COMPENSATION COMMISSION

AN ADDRESS BY DR. PHANEUF

Dr Louis E Phaneuf addressed the Buffalo Academy of Medicine, March 21, on The Management of Uterine Prolapse

DR. F M SHOCKLEY GOES TO STAMFORD HALL

Dr Francis M Shockley, of New York City and Orange, New Jersey, has been appointed Senior Assistant Physician at Stamford Hall Sanitarium, Stamford, Connecticut.

THE APPOINTMENT OF DR. GUY C RANDALL

Dr Guy C Randall has been appointed to the position of assistant superintendent of the Northampton State Hospital

He has been serving on the staff of the Danvers State Hospital

MORTALITY RATES

Telegraphic returns from 86 cities, with a total population of thirtyseven millions for the week ending March 17, indicate a mortality rate of 12.6 as against a rate of 12.1 for the corresponding week of last year. The highest rate (21.6) appears for Washington, D.C., and the lowest (6.5) for New Bedford, Mass. The highest infant mortality rate (19.3) appears for Duluth, Minn., and the lowest for Evansville, Ind., Fall River, Mass., Fort Wayne, Ind., Grand Rapids, Mich., Long Beach, Calif., Lowell, Mass., Miami, Fla., and South Bend, Ind., which reported no infant mortality.

The annual rate for 86 cities is 12.7 for the eleven weeks of 1934, as against a rate of 12.4 for the corresponding period of the previous year.

The rate in January was well below that of January, 1933. The higher average is due to the deaths in February and March, 1934. Deaths from automobile accidents are, thus far, much higher than was the case last year—*Bulletin of Department of Commerce*

FEDERATION OF AMERICAN SOCIETIES
FOR EXPERIMENTAL BIOLOGY

The Boston University School of Medicine was represented at the Federation of American Societies for Experimental Biology, recently held in New York City, by Dr Walter L Mendenhall, Dr Frederick F Yonkman, Dr Allan Winter Rowe, Dr David L Belding, Dr Frederick H. Pratt, Dr Carolyn Suden and Miss Marlon A. Reid

MASSACHUSETTS LEGISLATIVE
NOTES

PAROCHIALISM AGAIN

At the hearing before the Legislative Committee on Public Health on House Bill 755, Section 2, intro-

duced by Mr Dever of Cambridge, on petition of C Ruggles Smith, Registrar of the Middlesex College of Medicine and Surgery, there was attacked a provision of the Massachusetts statute (Section 2A, Chapter 112, General Laws) which has generally been regarded as a distinct advance in medical legislation in recent years. This Section permits the Board to accept (at its discretion) the examination of the National Board of Medical Examiners in lieu of its own examination. The same persons who opposed the giving of the discretionary power of approval of medical schools to the Massachusetts Board (House Bill 118) on the ground that "they knew so little about medical education", being by statute physicians who were not connected with a medical school, looked with disfavor on Section 2A, because the Examiners of the National Board are connected with medical schools. As the examinations of the National Board are accepted in over forty states, this recrudescence of narrow partisanship and parochialism is especially to be deplored as it may so easily become vicious.

An extended account of the hearing will appear in a later issue of the *Journal*

CORRESPONDENCE

SMALLPOX AND SUPPRESSION OF FACTS

March 30, 1934.

Editor, *New England Journal of Medicine*,

The following is from The Propaganda Menace by Frederick E Lumley, The Century Company, New York, 1933. The author quotes from E L Clarke, *The Art of Straight Living*, 1929. The quotation is as follows:

"SMALL-POX, THE PRESS AND THE ADVERTISING
MERCHANT"

"Early in the summer of 1924 a case of black small pox of a particularly virulent form was discovered in a large city of the North West. A news paper reporter at once interviewed the municipal health commissioner. The latter declared that the matter should be given wide publicity with a warning that only prompt vaccination of the thousands of unprotected persons could avert an epidemic. The reporter wrote an appropriate story on the subject. It was referred to the advertising department of his paper, which, in turn, submitted it to a group of retail merchants. At once three of the heaviest advertisers in the paper threatened to withdraw their advertising if the story were published. They felt it might hurt business."

"The story was not published, either by that paper or by any of its competitors. Business was protected, temporarily, but the epidemic came, and before a year had passed there were fourteen hundred cases and three hundred and fifty deaths from small-pox in that city!" Respectfully yours,

WM PEARCE COVES, M.D

cussion, elaborating the subject of the symposium Dr Frank Ober reviewed the afternoon's work

Dr Phemister presented his paper in the evening. This dealt primarily with a demonstration of the radiographic changes observed over a period of time following fractures of the neck of the femur. Dr Phemister's interpretations of the change in radiographic appearance were controlled in each case by photographic and histological examination of the diseased bone, where removed by operation.

Dr Phemister thought that a knowledge of the normal blood supply to the head and neck was the first prerequisite to understanding the mechanism of these changes. The anterior and posterior cervical vessels are said to supply the neck and possibly the head. There is some disagreement about the function of the vessels of the round ligament. It is thought that the inferior cervical artery supplies the medial side of the head and the superior cervical the lateral side of the head. Nussbaum disagrees that these vessels ever perforate the epiphyseal line but Dr Phemister thought that they probably did after fusion of the head and neck. The speaker showed slides of injected specimens to demonstrate this point. The capsule is also important in primary and collateral circulation. He stated that interference with the blood supply resulted in an aseptic necrosis of the bone and later proceeded to show the x-ray evidence of this process, as well as other pathological changes which follow.

There are four possible results in the femoral head from fracture of the neck of the femur: (1) a live head with union of the fracture, (2) a live head with non union of the fracture, (3) a dead head with union of the fracture, (4) a dead head with non union of the fracture. In Dr Phemister's experience he had treated 17 such fractures. Of these 14 resulted in dead heads and only three in live heads. His work was based on a study both from the standpoint of x-ray and the pathological specimens of 49 fractures. Of these cases the results were 17 live heads, 8 with union and 9 with non union, 32 dead heads, 4 with union and 28 with non union.

The pathological changes occurring at the site of fracture consist of necrosis of the cells of the fracture margins as a result of the friction of the non fixed fragments. After erosion, bony union occurs by a creeping replacement of dead bone along the fracture margins by fibroblastic osteogenic tissue. In time the callus completes the union of the fracture.

Where all tissues remain alive the x-ray shows a regional atrophy with no variation between the appearance of the head and that of the pelvis. The cartilage if undamaged remains intact and the joint space unchanged. Where union is complete the functional result of the hip is good. Dr Phemister thought that the most important point in securing union was in firm fixation of the fragments. Thus impacted fractures do well and are not observed to go through the process of necrosis and creeping replacement observed in other fractures.

The changes to be found by x-ray in the four possible results of fracture of the neck were shown by lantern slides. In each different case the interpretation was checked by the demonstration slides of the pathological specimens, where removed: (1) Live head with union. The density of the head was shown not to vary from that of regional atrophy demonstrable in the adjacent pelvis. (2) Live head with non union. Generalized atrophy with the density of the head not different than the pelvis. (3) Dead head with non union. The head having no blood supply retains its bony trabeculae and does not change in appearance, while the pelvis and neck become gradually less dense by comparison because of natural regional atrophy. Nature now attempts to repair the dead head by sending in blood vessels and connective tissue from remaining attachments such as round ligament and capsule. This in turn is followed by bone marrow and hemopoietic marrow. This creeping replacement is demonstrable in the x-ray by a gradual decrease in density spreading out from the available sources of blood supply to the dead head. The point of weight bearing is the last to show this replacement process. The cartilage remains intact for one to two years and then may break down. (4) Dead head with union. The x-ray over a period of time shows the same gradual creeping replacement. In such cases care must be exercised to delay weight bearing as this may break down the head after repair is apparently complete.

Dr Phemister showed a few results of other types of less common fractures. In a fracture of the base of the head died because the blood supply by way of the round ligament was thought to be insufficient. In a fracture of the greater trochanter there was death of the part of the head thought to be supplied by the posterior cervical artery. A dislocation of the hip without fracture was followed in one and a half years by creeping necrosis of the head probably because the round ligament had been torn and collateral circulation was insufficient to support the head.

In all of his work Dr Phemister thought that it was evident that the preservation, or loss of blood supply was the major factor in changes in the head of the femur. Yet in children there sometimes occurs aseptic necrosis without history of trauma. Then too, the condition known as Legg-Perthes' disease was difficult to understand.

Discussion was opened by Dr Brackett who suggested that longer immobilization of such fractures was a desirable procedure in treatment. Dr Cotton remarked that dead heads with union deserved protection but that dead heads without union had best be removed and the hip fixed. Dr Wilson mentioned that such pathological processes as Dr Phemister had shown also occurred in other regions which were not weight bearing, such as fracture dislocations of the shoulder and following arthroplasty where the bone is stripped. Dr Smith-Petersen agreed that blood supply is the first con-

PHYSICIANS' ART EXHIBIT

The Art and Craft Exhibit of the Physicians' Art Society is to be held at the Boston Medical Library beginning April 23 and extending through May 5

Physicians, dentists, hospital internes and medical students are eligible and should make application immediately to James F. Ballard at 3 The Fenway, Boston, Mass.

All forms of creative and applied art as well as artistic crafts will be considered by the Committee on Exhibits

Selections from the April exhibit will be shown in October during the meeting of the American College of Surgeons

The entry fee of \$4.00 for each exhibitor will include membership in the Physicians' Art Society, as well as the fees for both the April and October exhibits

The Committee on Exhibits consists of Drs. L. W. Hill, Eli Romberg, S. H. Sturgis, G. W. Taylor, S. C. Wiggin and J. D. Barney, President, and Mr. James F. Ballard, Secretary, ex officio

REPORTS AND NOTICES
OF MEETINGS

NEW ENGLAND HEART ASSOCIATION

A meeting of the New England Heart Association was held in the amphitheatre of the Children's Hospital on February 26. Drs. Paul Emerson and Hyman Green presided.

Dr. Green first presented for diagnosis three cases of congenital heart disease as they appeared during life and then to point out the great difficulty often encountered in making a correct diagnosis in these instances in children and infants, gave the findings after death. The first patient at autopsy showed the following anomalies: absent interatrial septum, defective auricular septum, a foramen ovale four millimeters in diameter, an absent superior vena cava atresia of the pulmonary artery, an absent spleen and situs inversus of the remaining abdominal viscera. The second case at post mortem showed an idiopathic hypertrophy, with a small patent foramen ovale. The third patient had a small patent foramen ovale, a patent ductus arteriosus, and a coarctation of the aorta of the infantile type.

Drs. Green and Emerson next proceeded with a classification of the 74 cases of congenital heart disease seen in the wards of the Children's Hospital in the last five years. All but six cases had either (1) septal defects one or more in various combinations (open foramen ovale, a defect in the interventricular septum or a patent ductus arteriosus) or (2) septal defects one or more with other cardiac defects. The six cases without septal defects were coarctation, one idiopathic hypertrophy, two pulmonary stenosis, one auriculoventricular defects, two. Tabulated the cases have been as follows: one septal defect, five cases, two septal defects, seven cases, three septal defects, seven cases, sep-

tal defects and coarctation of the aorta, eighteen cases, tetralogy of Fallot, five cases, septal defects and pulmonary stenosis or atresia, five cases, septal defects and transposition, eight cases, septal defects and aortic stenosis or atresia, with or without mitral stenosis, four cases, septal defects and defects of auriculoventricular valves, seven cases, tetralogy of Eisenmenger, one case, idiopathic hypertrophy, six cases, and microcardia, one case.

Dr. Maude Abbott of Montreal spoke briefly on the subject introduced by the two previous speakers. In her experience the correct diagnosis of congenital heart disease in infants under eight months of age is very difficult. A basal interauricular defect has been the most common cardiac finding in mongoloids in her series.

Dr. L. K. Diamond spoke briefly on cardiac findings in severe anemia. Out of a total of 200 patients with severe anemia (R.B.C. less than three million, hemoglobin less than 50 per cent) 40 of the children had a questionable cardiac thrill, a loud murmur, and enlargement. There were definite thrills in eight patients, diastolic murmurs in five. In 35 of the 40 cases the cardiac findings disappeared after recovery from the anemia. Five cases could not be followed up later. Dr. Diamond cautioned in closing that in the presence of a severe anemia or with a history of recent severe anemia the diagnosis of congenital heart disease, based on thrills, murmurs, or enlargements, should be made with reservation. Dr. Paul White concluded the meeting with a brief discussion of the problem of congenital heart disease, and noted the greater ease in diagnosis when we are dealing with adults with congenital cardiac defects. He summarized the findings in 15 cases of congenital heart disease seen at the Massachusetts General Hospital.

BOSTON ORTHOPEDIC CLUB

A meeting of the Boston Orthopedic Club was held on Monday, February 12, 1934, with a clinical program at the Children's Hospital in the afternoon and a paper in the evening at the Harvard Medical School. "Changes in the Head and Neck of the Femur Due to Traumatic and Vascular Disturbances" was the subject of the symposium, led by Dr. Dallas B. Phemister, Professor of Surgery, University of Chicago.

At the afternoon session a series of cases was presented and the discussion headed by Dr. Phemister. Dr. William Green first showed several instances of good results obtained with conservative treatment of slipped femoral epiphyses. Dr. Philip Wilson then presented a case of aseptic necrosis involving the head of the femur following dislocation and another following reduction of a slipped capital epiphysis. Dr. M. N. Smith Petersen reviewed a case of fractured neck of the femur followed by non-union with necrotic head in which he had obtained union, and Dr. Arthur Legg spoke briefly about the epiphyseal changes in coxa plana. Dr. Frederick Cotton followed with further case reviews and dis-

cussion, elaborating the subject of the symposium Dr Frank Ober reviewed the afternoon's work.

Dr Phemister presented his paper in the evening. This dealt primarily with a demonstration of the radiographic changes observed over a period of time following fractures of the neck of the femur. Dr Phemister's interpretations of the change in radiographic appearance were controlled in each case by photographic and histological examination of the diseased bone where removed by operation.

Dr Phemister thought that a knowledge of the normal blood supply to the head and neck was the first prerequisite to understanding the mechanism of these changes. The anterior and posterior cervical vessels are said to supply the neck and possibly the head. There is some disagreement about the function of the vessels of the round ligament. It is thought that the inferior cervical artery supplies the medial side of the head, and the superior cervical the lateral side of the head. Nussbaum disagrees that these vessels ever perforate the epiphyseal line, but Dr Phemister thought that they probably did after fusion of the head and neck. The speaker showed slides of injected specimens to demonstrate this point. The capsule is also important in primary and collateral circulation. He stated that interference with the blood supply resulted in an aseptic necrosis of the bone and later proceeded to show the x-ray evidence of this process as well as other pathological changes which follow.

There are four possible results in the femoral head from fracture of the neck of the femur: (1) a live head with union of the fracture, (2) a live head with non union of the fracture, (3) a dead head with union of the fracture, (4) a dead head with non union of the fracture. In Dr Phemister's experience he had treated 17 such fractures. Of these 14 resulted in dead heads and only three in live heads. His work was based on a study both from the standpoint of x-ray and the pathological specimens of 49 fractures. Of these cases the results were 17 live heads, 8 with union and 9 with non union, 32 dead heads, 4 with union, and 28 with non union.

The pathological changes occurring at the site of fracture consist of necrosis of the cells of the fracture margins as a result of the friction of the unfixed fragments. After erosion, bony union occurs by a creeping replacement of dead bone along the fracture margins by fibroblastic osteogenic tissue. In time the callus completes the union of the fracture.

Where all tissues remain alive the x-ray shows a regional atrophy with no variation between the appearance of the head and that of the pelvis. The cartilage if undamaged remains intact and the joint space unchanged. Where union is complete the functional result of the hip is good. Dr Phemister thought that the most important point in securing union was in firm fixation of the fragments. Thus impacted fractures do well and are not observed to go through the process of necrosis and creeping replacement observed in other fractures.

The changes to be found by x-ray in the four possible results of fracture of the neck were shown by lantern slides. In each different case the interpretation was checked by the demonstration slides of the pathological specimens, where removed: (1) Live head with union. The density of the head was shown not to vary from that of regional atrophy demonstrable in the adjacent pelvis. (2) Live head with non union. Generalized atrophy with the density of the head not different than the pelvis. (3) Dead head with non union. The head having no blood supply retains its bony trabeculae and does not change in appearance, while the pelvis and neck become gradually less dense by comparison because of natural regional atrophy. Nature now attempts to repair the dead head by sending in blood vessels and connective tissue from remaining attachments such as round ligament and capsule. This in turn is followed by bone marrow and hemopoietic marrow. This creeping replacement is demonstrable in the x-ray by a gradual decrease in density spreading out from the available sources of blood supply to the dead head. The point of weight bearing is the last to show this replacement process. The cartilage remains intact for one to two years and then may break down. (4) Dead head with union. The x-ray over a period of time shows the same gradual creeping replacement. In such cases care must be exercised to delay weight bearing as this may break down the head after repair is apparently complete.

Dr Phemister showed a few results of other types of less common fractures. In a fracture of the base of the head died because the blood supply by way of the round ligament was thought to be insufficient. The six cases without septal defects were coarctation, one idiopathic hypertrophy, two pulmonary stenosis, one auriculoventricular defects, two tabulated, the cases have been as follows: one septal defect, five cases; two septal defects, seven cases; three septal defects, seven cases; sep-

tal defects and coarctation of the aorta, eighteen cases; tetralogy of Fallot, five cases; septal defects and pulmonary stenosis or atresia, five cases; septal defects and transposition, eight cases; septal defects and aortic stenosis or atresia, with or without mitral stenosis, four cases; septal defects and defects of auriculoventricular valves, seven cases; tetralogy of Eisenmenger, one case; idiopathic hypertrophy, six cases, and microcardia, one case.

Dr. Maude Abbott of Montreal spoke briefly on the subject introduced by the two previous speakers. In her experience the correct diagnosis of congenital heart disease in infants under eight months of age is very difficult. A basal interauricular defect has been the most common cardiac finding in mongoloids in her series.

Dr. L. K. Diamond spoke briefly on cardiac findings in severe anemia. Out of a total of 200 patients with severe anemia (R.B.C. less than three million, hemoglobin less than 50 per cent) 40 of the children had a questionable cardiac thrill, a loud murmur, and enlargement. There were definite thrills in eight patients, diastolic murmurs in five. In 35 of the 40 cases, the cardiac findings disappeared after recovery from the anemia. Five cases could not be followed up later. Dr. Diamond cautioned in closing that in the presence of a severe anemia or with a history of recent severe anemia the diagnosis of congenital heart disease, based on thrills, murmurs, or enlargements, should be made with reservation. Dr. Paul White concluded the meeting with a brief discussion of the problem of congenital heart disease, and noted the greater ease in diagnosis when we are dealing with adults with congenital cardiac defects. He summarized the findings in 15 cases of congenital heart disease seen at the Massachusetts General Hospital.

BOSTON ORTHOPEDIC CLUB

A meeting of the Boston Orthopedic Club was held on Monday, February 12, 1934, with a clinical program at the Children's Hospital in the afternoon and a paper in the evening at the Harvard Medical School. "Changes in the Head and Neck of the Femur Due to Traumatic and Vascular Disturbances" was the subject of the symposium, led by Dr. Dallas B. Phemister, Professor of Surgery, University of Chicago.

At the afternoon session a series of cases was presented and the discussion headed by Dr. Phemister. Dr. William Green first showed several instances of good results obtained with conservative treatment of slipped femoral epiphyses. Dr. Philip Wilson then presented a case of aseptic necrosis involving the head of the femur following dislocation and another following reduction of a slipped capital epiphysis. Dr. M. N. Smith Petersen reviewed a case of fractured neck of the femur followed by non union with necrotic head in which he had obtained union, and Dr. Arthur Legg spoke briefly about the epiphyseal changes in coxa plana. Dr. Frederick Cotton followed with further case reviews and dis-

cussion, elaborating the subject of the symposium Dr Frank Ober reviewed the afternoon's work.

Dr Phemister presented his paper in the evening. This dealt primarily with a demonstration of the radiographic changes observed over a period of time following fractures of the neck of the femur. Dr Phemister's interpretations of the change in radiographic appearance were controlled in each case by photographic and histological examination of the diseased bone where removed by operation.

Dr Phemister thought that a knowledge of the normal blood supply to the head and neck was the first prerequisite to understanding the mechanism of these changes. The anterior and posterior cervical vessels are said to supply the neck and possibly the head. There is some disagreement about the function of the vessels of the round ligament. It is thought that the inferior cervical artery supplies the medial side of the head and the superior cervical the lateral side of the head. Nussbaum disagrees that these vessels ever perforate the epiphyseal line but Dr Phemister thought that they probably did after fusion of the head and neck. The speaker showed slides of injected specimens to demonstrate this point. The capsule is also important in primary and collateral circulation. He stated that interference with the blood supply resulted in an aseptic necrosis of the bone, and later proceeded to show the x-ray evidence of this process as well as other pathological changes which follow.

There are four possible results in the femoral head from fracture of the neck of the femur: (1) a live head with union of the fracture, (2) a live head with non-union of the fracture, (3) a dead head with union of the fracture, (4) a dead head with non-union of the fracture. In Dr Phemister's experience he had treated 17 such fractures. Of these 14 resulted in dead heads and only three in live heads. His work was based on a study both from the standpoint of x-ray and the pathological specimens of 49 fractures. Of these cases the results were 17 live heads, 8 with union and 9 with non-union, 32 dead heads, 4 with union and 28 with non-union.

The pathological changes occurring at the site of fracture consist of necrosis of the cells of the fracture margins as a result of the friction of the non-fixed fragments. After erosion bony union occurs by a creeping replacement of dead bone along the fracture margins by fibroblastic osteogenic tissue. Intermal callus completes the union of the fracture.

Where all tissues remain alive the x-ray shows a regional atrophy with no variation between the appearance of the head and that of the pelvis. The cartilage if undamaged remains intact and the joint space unchanged. Where union is complete the functional result of the hip is good. Dr Phemister thought that the most important point in securing union was in firm fixation of the fragments. Thus impacted fractures do well and are not observed to go through the process of necrosis and creeping replacement observed in other fractures.

The changes to be found by x-ray in the four possible results of fracture of the neck were shown by lantern slides. In each different case the interpretation was checked by the demonstration slides of the pathological specimens, where removed: (1) Live head with union. The density of the head was shown not to vary from that of regional atrophy demonstrable in the adjacent pelvis. (2) Live head with non-union. Generalized atrophy with the density of the head not different than the pelvis. (3) Dead head with non-union. The head having no blood supply retains its bony trabeculae and does not change in appearance while the pelvis and neck become gradually less dense by comparison because of natural regional atrophy. Nature now attempts to repair the dead head by sending in blood vessels and connective tissue from remaining attachments such as round ligament and capsule. This in turn is followed by bone marrow and hemopoietic marrow. This creeping replacement is demonstrable in the x-ray by a gradual decrease in density spreading out from the available sources of blood supply to the dead head. The point of weight bearing is the last to show this replacement process. The cartilage remains intact for one to two years and then may break down. (4) Dead head with union. The x-ray over a period of time shows the same gradual creeping replacement. In such cases care must be exercised to delay weight bearing as this may break down the head after repair is apparently complete.

Dr Phemister showed a few results of other types of less common fractures. In a fracture of the base of the head died because the blood supply by way of the round ligament was thought to be insufficient. In a fracture of the greater trochanter there was death of the part of the head thought to be supplied by the posterior cervical artery. A dislocation of the hip without fracture was followed in one and a half years by creeping necrosis of the head probably because the round ligament had been torn and collateral circulation was insufficient to support the head.

In all of his work Dr Phemister thought that it was evident that the preservation, or loss of blood supply was the major factor in changes in the head of the femur. Yet in children there sometimes occurs aseptic necrosis without history of trauma. Then too the condition known as Legg-Perthes' disease was difficult to understand.

Discussion was opened by Dr Brackett who suggested that longer immobilization of such fractures was a desirable procedure in treatment. Dr Cotton remarked that dead heads with union deserved protection but that dead heads without union had best be removed and the hip fixed. Dr Wilson mentioned that such pathological processes as Dr Phemister had shown also occurred in other regions which were not weight bearing such as fracture dislocations of the shoulder and following arthroplasty where the bone is stripped. Dr Smith Petersen agreed that blood supply is the first con-

sideration but pointed out that in congenital dislocation of the hip the round ligament is known to be of no use and still after reduction by the closed method is often a progressive deformity of the head. This he thought due to destruction of the cartilage by pressure because of the new position.

In concluding, Dr. Phemister briefly mentioned principles of treatment, and thought a fine choice often was necessary to insure the best result. In dead heads with union, too much use caused necrosis but too little use often resulted in non union. In dead heads without union in old people, the best procedure is removal of the head and fusion of the hip. Absorption of the neck of the femur following fracture he thought to be the result of a lack of osteogenic function of the periosteum of the neck, although others think that synovial fluid in the fracture line interferes with union. He knew of no explanation for the necrosis occurring in arthroplasty. He agreed with Dr. Smith Petersen that compression might interfere with the blood supply to the head of the femur.

GREATER BOSTON MEDICAL SOCIETY

A joint meeting of the Greater Boston Medical Society and the Staff of the Beth Israel Hospital was held on March 6, in the amphitheatre of the hospital. Professor Leopold Lichtwitz, Physician in Chief at the Montefiore Hospital for Chronic Diseases, in New York, was the principal speaker. The subject was "The Dynamics of Blood Dyscrasias." Dr. M. E. Barron, President of the Society, presided.

Dr. Lichtwitz attacked the problem of blood dyscrasias in a manner novel to most considerations of the subject. The blood and its cells are not to be viewed only as seen through the microscope, but in a much broader sense. In addition to the actual cell counts as obtained by the ordinary methods the blood volume and total number of cells are of utmost importance. Even though the percentage of hemoglobin and the red blood count be normal, in the presence of oligemia there thus may be anemia. Numerous cases were depicted in illustration. The size of the red blood cells and the great changes in the total surface of the cells in anisocytosis was another point that was emphasized. The importance of this factor in gaseous exchange cannot be overemphasized. The concept of "inactive hemoglobin" was touched upon and the disproportion in polglobulia between hemoglobin content and oxygen carrying capacity was mentioned. After about 150,000 gaseous exchanges the life of the normal red blood cell ends, due to colloid changes in the stroma consequent on chemical activity. This type of aging is an attribute of all colloidal systems, and in the particular instance of blood there is an average destruction of about 100 cc daily. The life of the red blood cell must be less in anemia because of the greater amount of work (gaseous exchange) necessary for each cell. The only known method for studying the colloidal state of the erythrocyte on a

quantitative basis is by a study of cell fragility. After hemorrhage and in anemia the cells are younger and the more fragile, or old, forms are missing. The 'fragility curve' of the red blood cells is thus important in the study of blood-dyscrasias. Blood renovation is explained on the concept that higher frequency of oxygen combination means increased destruction and then formation of new cells. The paper was discussed by Drs. Maurice B. Strauss, William E. Dameshek, William B. Castle, and Joseph C. Aub. All of the speakers emphasized their interest in the viewpoint presented. Drs. Castle and Aub questioned somewhat the accuracy of fragility tests in determining the age of red blood cells, and wondered whether other factors might not be important in fragility as well as mere age, and whether fragility really was a direct measure of age. In closing the meeting Dr. Lichtwitz summarized his views by saying that the duration of erythrocytes is not a function of time but a function of reactions.

HARVARD MEDICAL SOCIETY

The next meeting of the Harvard Medical Society will be held in the Peter Bent Brigham Hospital Amphitheatre (Van Dyke Street entrance), Tuesday evening, April 10, at 8 15 P M.

PROGRAM

Presentation of Cases

The Incidence, Etiology and Treatment of Nutritional Anemia. By L. S. P. Davidson, M.D., F.R.C.P.E., F.R.S.E., Professor of Medicine at the University of Aberdeen.

Dr. George R. Minot will preside.

JOHN HOMANS, M.D., *Secretary*

WILLIAM HARVEY SOCIETY

The next meeting of the William Harvey Society will be held Friday, April 13, in the Auditorium of the Beth Israel Hospital, Boston, at 8 P M.

PROGRAM

Speaker: Dr. Albert A. Epstein, of New York City.
Subject: "Diseases of the Kidney in General Practice."

Chairman: Dr. Henry Baker, Assistant Professor of Medicine, Tufts College Medical School.

MASSACHUSETTS GENERAL HOSPITAL

A Clinical Meeting of the Staff of the Massachusetts General Hospital will be held in the Moseley Memorial Building, on Thursday, April 12, 1934, at 8 15 P M.

CLINICOPATHOLOGICAL CONFERENCE

Three cases will be presented.

Differential diagnosis by Dr. Frederick T. Lord, Dr. Arthur W. Allen and Dr. Fuller Albright.
Pathological discussion by Dr. Tracy B. Mallory.
Physicians, Medical Students, Nurses and Social Workers are cordially invited.

COMMITTEE ON HOSPITAL MEETINGS

NEW ENGLAND ASSOCIATION OF THE JOHNS HOPKINS ALUMNI

The annual meeting of the New England Association of the Johns Hopkins Alumni will be held Saturday evening, April 14, at the University Club, Boston. Dinner will be served at 7 P.M. Dr. E. K. Marshall, Jr., Professor of Pharmacology, will address the meeting after the dinner.

MARSHALL FULTON, M.D. *Secretary*
721 Huntington Avenue, Boston.

PHI DELTA EPSILON FRATERNITY

On Monday night, April 16, the Phi Delta Epsilon Fraternity of Boston University School of Medicine will hold another of its open meetings.

Dr. Frank H. Lahey of the Lahey Clinic will speak on 'Thyroid Disease Its Diagnosis and Management' and Dr. Lewis M. Huxthal, of the Lahey Clinic will talk on 'Myxedema, Hypometabolism, and Blood Cholesterol.' Dr. Allan Winter Rowe, Director of Clinical Research of the Evans Memorial Hospital will lead the discussion.

BOSTON UNIVERSITY SCHOOL OF MEDICINE

WILL CONDUCT A CLINICAL MEETING
AT BOSTON CITY HOSPITAL

Dr. E. Starr Judd, Professor of Surgery, University of Minnesota, School of Medicine, and Surgeon at the Mayo Clinic Rochester, Minnesota, will give a clinic in the Cheever Amphitheatre Boston City Hospital, at 11 o'clock on Monday, April 16, under the auspices of the Department of Surgery of Boston University School of Medicine.

His subject will be Surgical Diseases of the Biliary Tract. Drs. Horace Binney of the Boston City Hospital, Arthur W. Allen of the Massachusetts General Hospital and Elliott C. Cutler of the Peter Bent Brigham Hospital will take part in the discussion.

Physicians and medical students are invited to attend.

OTTO J. HERMANN,
WILLIAM R. MORRISON,
DWIGHT O'HARA

*Committee on Clinics,
Boston City Hospital*

SOUTH END MEDICAL CLUB

The regular meeting of the South End Medical Club will be held at the office of the Boston Tuberculosis Association 554 Columbus Avenue Boston on Tuesday April 17 1934, at 12 noon. The speaker will be Richard M. Smith M.D. Assistant Professor of Pediatrics and Child Hygiene, Harvard Medical School Visiting Physician at the Infants Hospital Associate Physician at the Children's Hospital. His subject will be Acute Abdominal Conditions in Children. All physicians are cordially invited to attend. The usual luncheon will be served.

NEW ENGLAND SOCIETY OF PSYCHIATRY

April 27—The New England Society of Psychiatry will hold its Spring meeting at the Psychiatric Clinic of the Boston State Hospital, Dorchester Center, Massachusetts.

HARLAN L. PAINE, M.D., *Secretary-Treasurer*

AMERICAN HEART ASSOCIATION

The Tenth Scientific Session of the American Heart Association will be held on Tuesday, June 12, 1934, from 9:30 to 5:30 P.M., at the Cleveland Hotel, Cleveland Ohio. The program will be devoted to arteriosclerotic heart disease.

ANNUAL MEETING OF THE MASSACHUSETTS TUBERCULOSIS LEAGUE

The twenty-second Annual Meeting of the Massachusetts Tuberculosis League Inc. will be held at Hotel Statler, Boston on Thursday, April 12. Dr. Frederick T. Lord, President, will preside at the sessions which will begin at 11:00 A.M. in Parlor B on the Mezzanine Floor.

The first session will consist of the annual address of the President, reports of the Executive Secretary, the Educational Secretary and the Treasurer.

At noon there will be a meeting of the Corporation for election of Officers and Directors.

At 12:45 P.M. the annual luncheon meeting will be held in the Georgian Room at which the speakers will be Dr. Henry D. Chadwick, State Commissioner of Public Health and Dr. Kendall Emerson, Managing Director of the National Tuberculosis Association.

Members of the twenty-eight Affiliated Organizations of the League throughout the State are invited to attend the sessions.

The price of the luncheon will be \$1.00. Reservations should be sent to the Massachusetts Tuberculosis League 1148 Little Building, Boston—Telephone, Hancock 5480.

SOCIETY MEETINGS, CONGRESSES AND CONFERENCES

April 5—Faulkner Hospital Clinical Meeting will be held at 5 P.M.

April 5—Hart Hospital Inc. Staff Meeting will be held at 8:30 P.M.

April 5—New England Hospital for Women and Children will hold its regular clinico-pathological conference at 7:30 P.M.

April 10—Harvard Medical Society. See page 778.

April 11—New England Dermatological Society will meet at the Boston City Hospital at 3 P.M.

April 12—Massachusetts Tuberculosis League. See notice above.

April 12—Massachusetts General Hospital. Clinical meeting of the Staff. See page 778.

April 13—William Harvey Society. See page 778.

April 13 20 and 27—Salmon Memorial Lectures. See page 443 issue of February 22.

April 14—New England Association of the Johns Hopkins Alumni. See notice elsewhere on this page.

April 16—Phi Delta Epsilon Fraternity. See notice elsewhere on this page.

April 16—Boston University School of Medicine to Conduct a Clinical Meeting at Boston City Hospital. See notice elsewhere on this page.

April 16-20—The American College of Physicians will hold its Eighteenth Annual Clinical Session in Chicago.

at the Palmer House For information write Mr E R Loveland Executive Secretary, 133-135 South 36th Street, Philadelphia, Pa

April 17—South End Medical Club See page 779

BOOK REVIEWS

International Clinics Edited by Louis Hamman, M.D. Volume IV Forty Third Series 1933 Published by J B Lippincott Company 317 Pages

Since Dr Hamman has assumed editorial control, the major portion of each volume of these clinics has been devoted to a symposium on some subject. This is a great advantage to the practicing physician as most of the articles in these symposia are reviews of the work of various men who have been major contributors in these fields. Bringing the subject matter up to date so promptly gives it a distinct advantage over the textbook. The symposium in this particular volume relates to the use of endocrine gland products as thyroid, pituitary and supra renal substance and insulin with a discussion of the experimental and clinical background.

There is also an excellent article on the treatment of obesity by Wilder. Finland reviews at length the important problem of the serum treatment in pneumonia. Although the section on surgery is considerably less prominent it has some good articles. In the field of dermatology there is a review of Lupus Erythematosus Disseminatus.

Industrial Health Service By LEVERETT DALL BRISOL. Published by Lea & Febiger, Philadelphia 170 Pages Price \$2.00

The author divides this 170-page manual into three parts. Part I presents an employee health scheme for an industrial plant. Part II relates to methods for carrying out the scheme. Part III gives "what everybody ought to know" information regarding health.

The book is written in the light of a wide and varied experience. The author's fundamentals are sound and his medical advice is refreshingly good.

The book seems well calculated to serve its purpose as a guide for industrial managers and employers generally and to be useful to anybody.

Medical Art Calendar, 1934 Published by J. Phillip Kruseman The Hague. Price \$1.50

This well known Dutch calendar which apparently is a unique contribution to the history of medicine has been published for a number of years. In it are found, attractively reproduced, copies of famous pictures. It is well worth the modest price charged for it.

NUMBER 15

HERNIA OF THE DIAPHRAGM

Esophageal Type In Adults

BY PHILEMON E. TRUESDALE, M.D.*

HERNIA of the stomach through the esophageal hiatus occurring in adults is now recognized not infrequently by internists, gastroenterologists and roentgenologists. As a rule the history presents nothing characteristic. These patients complain of indigestion. Distress comes on soon after deglutition and is referred to a point high in the epigastrium or in the substernal region. There may be attacks characterized by pain which radiates to the shoulder, the axilla or the back. Pain may encircle the thorax, appear in the form of precordial distress with tachycardia, dyspnea, nausea, and vomiting. Many of these patients have secondary anemia. A. V. Bock has reported a series of this type.

Diseases with which this form of hernia is commonly confused are cholelithiasis, peptic ulcer, angina pectoris and esophageal stricture.

Acute attacks of pain are due to distention of that portion of the stomach which is above the enlarged esophageal opening of the diaphragm.

The following is the report of a case of this type. Dr. Samuel Morein, the patient's physician, submitted this carefully taken history which we have embodied in the hospital record.

E. C. housewife, aged 48 years, was admitted to the Truesdale Hospital September 9, 1933. She complained of indigestion of about twenty years duration. This was manifested chiefly by a bloated and crowded feeling in the epigastrium and the lower left chest, and palpitation. Associated with these was a low substernal pain which was gnawing in character and almost constant. These symptoms were mild at first, but have progressively become more severe in character of late years.

Immediately after deglutition the distress becomes more noticeable and often she has to leave the table during her meals and walk around for relief. Alkalis, laxatives or enemas have no effect in relieving her distress. Green vegetables such as celery and lettuce may bring on a severe attack. She has had attacks manifested by symptoms varying in severity, some were mild while others were severe. Attacks have come on during the night, rousing her from a sound sleep. At times she has induced vomiting to obtain relief from her distress. Some of her pain radiates to the back, left side, left shoulder and down the arm. She also has had attacks that

were accompanied by marked epigastric pain radiating to the back, bloating, belching, nausea and vomiting. On many occasions she was obliged to call a physician and have morphia administered hypodermically to obtain relief from her distress. She experiences palpitation and some dyspnea after the ingestion of a heavy meal or if she retires soon after overeating. She has been constipated for many years but manages to have good movements by taking mild laxatives daily. On several occasions she noticed blood in her vomitus, varying in quantity from streaks to a few teaspoonfuls, and many times she observed that her stools were rather dark, grayish in color. She smoked cigarettes to excess. Her nervous system was fairly stable for one who has a constant gastric disturbance.

Past History. She has had several abdominal operations. In 1914 she had a hysterectomy, also one ovary and the appendix were removed at the same time. During her convalescence she had an attack of pleurisy. In 1926 or 1927 she had a cystic tumor removed from her pelvis. In 1932 she had a tonsillectomy on account of getting frequent colds. She had been treated by many doctors for various conditions. At times gall bladder disease was suspected also myocarditis, anemia and migraine. She had had treatment with temporary relief. About four years ago she was under observation in a very good clinic, at which time a complete x-ray study was made of her chest and gastro-intestinal tract. She was then told she was suffering from colitis. She gave no history of any accidental injuries.

Family History. She has two children, aged 24 and 21, living and in good health. She had no miscarriages. Her husband is living and well. Her family history is otherwise irrelevant.

Physical examination revealed a rather stocky, well developed and nonrushed woman of 48, height, five feet, weight 141, and somewhat anemic in appearance. Her hemoglobin was 70 to 75 per cent and the red blood count was 4,000,000. Her heart and lungs appeared normal except that during the examination splashing sounds were elicited in the central and lower left chest. She was definitely tender in the epigastrium. There were several abdominal scars from her previous operations. No congenital abnormality was noted. Rectal examinations revealed several hemorrhoids. Her blood pressure was 140/80. The blood Wassermann was negative. Her urine was negative. The basal metabolic rate was -13 per cent. Six stools were examined and they were always strongly positive for blood by both the guaiac and benzidin tests.

When the patient consulted Dr. Samuel Morein of Providence, R. I., a complete roentgenographic study of the chest and abdomen was made. Our examinations have corroborated his in all details.

Finorosopic examination of her chest (figure 1), while the patient was standing, revealed a shadow with most of it overlapped by the heart shadow. The heart and lungs appeared normal. After the administration of a barium meal, with the patient

*Truesdale, Philemon E.—Surgeon, Truesdale Clinic, Fall River, Massachusetts. For record and address of author see "This Week's Issue," page 51.

standing, this abnormal shadow was found to be a diaphragmatic hernia of the esophageal orifice type, involving one third of the stomach. The barium

meal was seen progressing down into the lower esophagus, entering the cardiac orifice of the stomach rather slowly, and then progressing upward and filling the upper chamber of the stomach, which was contained in the hernia above the diaphragm. It was also noted that some of the barium was percolating slowly through a constricted portion of the stomach, into the larger lower portion below the

FIGURE 1

FIGURE 3 Postoperative film

FIGURE 2 Preoperative roentgenogram.

diaphragm. This hernia was incarcerated, as there was no reduction by changing the position of the patient, by manipulation, or with deep inspiration. The stomach was otherwise normal. The duodenum appeared normal.

At six hours there was a minute residue of barium left in the hernia. The small intestines and colon appeared normal. The Graham test revealed a normal functioning gall bladder with no evidence of calculi.

The findings in the examination were made clear to the patient and a trial period of medical treatment adopted. This consisted essentially of a dietary régime with antispasmodics, sedatives, and some form of iron medication. During the period of three months she improved slightly but complained of living a life of very limited activity and of general weakness, also of a feeling at times of faintness and dizziness on standing. She also stated that even talking for a while became an exertion. 'Every thing seemed to be an effort.' She felt much better when she abstained from food or when she was hungry.

Her weight on August 17, 1933 was 135 lbs, a loss of 6 lbs in two months. Stool examination on a meat free diet gave a 4 plus guaiac reaction. Her hemoglobin was 70 per cent, red blood corpuscles 3,670,000, and white corpuscles 8,000.

It was therefore decided that surgical intervention would be the appropriate treatment in this case. The impression of the internist, Dr J. A. Mc-

Adams who examined this patient in our clinic was as follows "I am certain that I could not have made a diagnosis of diaphragmatic hernia in this case from the physical signs alone. While these sounds are compatible with a protrusion of a hollow viscus through an opening in the diaphragm the history seems to me to arouse more suspicion than do the physical signs. To be sure, the signs at the base of the left pleural cavity indicate definitely less aeration of the lung than at the right base. Transmission of voice sounds is diminished at the left base. On percussion there is very little difference between the two sides, possibly more of a hyporesonance over the mid region of the left chest posteriorly above the herniated stomach. The heart is not perceptibly displaced. There is a higher level of hyperresonance on the chest wall anteriorly, although not higher than frequently observed in the presence of a distended stomach. Tactile fremitus appears to be but slightly different on the two sides. The gaseous sounds and gurgling are not sufficiently marked to be of any particular help."

This part of the record is reported to show that chances of failure to detect this type of diaphragmatic hernia are real even when the examiner is proficient and careful. The combination of history and physical signs was sufficient to "arouse suspicion." The evidence must be sufficient to arouse suspicion in the mind of the internist or gastroenterologist in order that he may direct the roentgenologist to focus his attention upon the cardiac portions of the esophagus and stomach. Otherwise, hernia might exist and escape recognition even in the hands of an expert roentgenologist. The late Dr. L. B. Morrison¹ of Boston reported a large series of these cases which he had discovered, and described a valuable method of x-ray examination whenever the condition was suspected.

We operated upon this patient September 11th. Under positive pressure gas oxygen anesthesia, the left thoracic cage was opened by half a rectangle incision over the 6th and 7th ribs extending from the left costal cartilage to the posterior angle of the rib. The cardiac portion of the stomach was found protruding upwards through the esophageal aperture, the long diameter of which measured approximately 12 cm. The stomach was covered by a thin membranous sac, apparently adherent, to form a hernia vera. This bulging hollow viscus was adherent to the overlying lung, the left surface of the pericardium and the margin of the opening in the diaphragm.

Owing to the position of the left inferior azygos minor vein with its branches, considerable difficulty was met in separating the collar of fibrous bands attaching the stomach to the lung, pericardium and diaphragm. After this troublesome complication was overcome, the stomach was reduced to its normal position below the diaphragm. The large aperture was finally closed by nine or ten interrupted su-

tures of silk. The opening in the chest wall was then closed by mass interrupted sutures of silver wire.

The early convalescence was accompanied by considerable pain apparently in the thoracotomy wound. The temperature did not rise above 100 degrees. The pulse remained at 120 for three days, then gradually fell to 80. After the fourth day the patient remained on house diet without discomfort. She was discharged October 14th.

Two cases of this type of hernia have been published by the author in the *New England Journal of Medicine* under the dates of June 25, 1931 and September 1, 1932 respectively.

While operative treatment offers the only means of cure of a diaphragmatic hernia of any type, surgery is not indicated in this particular form until medical treatment has had a fair trial. Operation should not be undertaken upon patients who ordinarily would be considered Class B risks.

It requires careful discrimination to determine whether in a given case the symptoms are due to the diaphragmatic hernia. Before deciding to proceed surgically all other causes of the symptoms should be eliminated. It is to be borne in mind also that this form of hernia has been found at autopsy where no history suggestive of its existence during life had been obtained.

It is realized too, that considerable skepticism exists in the minds of many internists and surgeons about the wisdom of undertaking the transthoracic operations for repair of esophageal hernia when it is discovered at or beyond the meridian of life. Time and experience will determine the issue. Thus far we have operated upon six patients with this type of hernia. No deaths have occurred among this group. The series is too small to warrant deductions pertaining to mortality, cure of the condition or technique of the operation itself. Each case appears to be of sufficient significance to record individually. In subsequent reports of the remaining three cases of this series we may feel sufficiently justified to dwell at greater length upon the symptomatology, etiology of pain, technique in the operation and incidentally the important services rendered by the internist, the roentgenologist, the anesthetist, and operating room assistants, the combination of whose support has made it possible for a surgeon to accomplish a difficult task.

HEREDITARY ECTODERMAL DYSPLASIA OF THE
ANHIDROTIC TYPE, WITH CASE REPORT

BY J MARK HIEBERT, M.D.,* AND JOSEPH GARLAND, M.D.*

HEREDITARY ectodermal dysplasia of the anhidrotic type was first described by Thurman¹ in England in 1848. Detailed and elaborate descriptions are given by Weech² who gave the condition its name. In his report Weech reviews the literature of nine cases, adding two more to the list. Smith³, more recently, has reviewed the literature completely, including a thorough description of the symptomatology, etiology and diagnosis of the condition, and reports the sixteenth case.

Various forms of ectodermal defects have been noted. Clouston⁴ analyzed one hundred and nineteen cases occurring in six generations of one family, none, however, being of the anhidrotic type. Goeckermann⁵ first recognized a group of cases which he called "high grade congenital ectodermal defect" in which there is not only a congenital absence of teeth and a hypotrichosis, but also a total absence of sweat glands and an almost total absence of sebaceous glands.

MacKee and Andrews⁶ described the clinical characteristics of this condition as follows: congenital absence of sweat glands, absence of pilosebaceous apparatus over most of the body, marked dental aplasia, depressed nasal bridge, atrophic rhinitis, prominent supra-orbital ridge, thick protrusive lips, thin, glossy, smooth, dry skin, papular lesions on the face and heat intolerance.

The following case represents the anhidrotic type of hereditary ectodermal dysplasia.

J. B., male, aged five years and ten months was referred to the Children's Medical Department of the Massachusetts General Hospital, October 30, 1933, from the Forsyth Dental Infirmary, because of abnormal dentition. He is the oldest of three children, the two younger being apparently normal.

Family History. The father aged 32 and the mother aged 29 are living and well. A paternal granduncle is said to have been edentulous until the age of five, after which a normal set of permanent teeth developed. No similar anomalies have been noted in any other member of the family.

Past History. The patient was normally delivered at term weighing seven pounds. Aside from a pale skin no abnormalities were noted at birth although his cry was never more than a whine. He was nursed from the beginning with supplementary feedings started at three months.

Developmental. He held his head up at four months, sat alone at eight months and walked at seventeen months. The first tooth was cut at eleven months and now at the age of five years and ten

months, he has in the mandible two canines, and in the maxilla one incisor, two canines and two molars. All of the teeth are tusk shaped and widely spaced. In spite of this imperfect dentition he masticates his food in a fairly effective manner.

Present Condition. The patient never perspires, even in the hottest weather and consequently suffers extreme discomfort at times in the summer. His hair has always been sparse and of exceedingly fine texture, with a tendency to break and with scattered areas of alopecia especially in the right parietal region. The palms and soles are always dry and scaly. Since birth he has had a chronic rhinitis. His voice has always been hoarse and he has frequent attacks of complete aphonia.

Physical Examination. Examination shows a well developed normally nourished boy. The height

is 42½ inches, the weight 42 pounds. The skin is dry, hot and parchmentlike to the touch, especially over the shins and thighs. There is no evidence of any perspiration in the axillae or in the folds of the skin.

The head is normally developed with a circumference of twenty inches. The supra-orbital ridges are somewhat prominent. The auricles show no abnormalities, the canals are plugged with a dry, crusty cerumen. The eyebrows are absent, although a few scattered eye lashes are present. The nose is wide and the bridge low. The turbinates and mucous membranes are pale with a moderate amount of yellowish discharge present. The lips are thick, everted, dry and wrinkled. The buccal membranes and pharynx appear normal.

The most striking feature is the peculiar teeth,

*Hiebert J. Mark—Formerly House Officer Children's Medical Service Massachusetts General Hospital. Garland Joseph—Physician to Children's Medical Service Massachusetts General Hospital. For records and addresses of authors see This Week's Issue page 817.

there being in the mandible two canines only and in the maxilla one incisor two canines and two molars all of a peglike conical shape

Examination of the chest and abdomen reveals no abnormalities. The nipples are present. The genitals, extremities and nails appear normal.

Mentally the boy responds as a normal, happy alert child.

Laboratory Data

Urine specific gravity 1020 reaction acid
albumen negative sugar negative sedi-
ment no cells or casts

Red blood cells 4,900,000 white blood cells,
6,200 hemoglobin 75 per cent.

Blood smear neutrophils 65 per cent lym-
phocytes 30 per cent monocytes 4 per cent
basophils 1 per cent no variations in
staining reactions no stippling

Hinton negative

Intradermal tuberculin 1:1000 negative

Basal metabolic rate average plus 8 per cent.

Fasting blood sugar 97 mgm per 100 cc cho-
lesterol 154 mgm per 100 cc serum calcium
11.45 and serum phosphorus 4.48 mgm per
100 cc

Skin temperatures were taken as described by
Talbot

	Patient	Standard
Average temperature of face	35.2 C	33.2 C
" " trunk	37.1	35.5
" " extremi- ties	35.4	33.0

rectal temperature 37.8

The skin temperatures of our patient therefore equalled those of normal children with rectal temperatures of 40 C or 104.5 F (Skin Temperatures of Children Table No. 40)

A specimen of skin taken from the back between the shoulder blades was examined in a series of

Section of skin from patient's back showing absence of hair follicles, sweat or sebaceous glands.

sections. No hair follicles, sweat glands or sebaceous glands were found.

X-rays revealed four unerupted teeth in the mandible and two in the maxilla.

HYDRONEPHROSIS DUE TO SUBEPITHELIAL FIBROSIS TREATMENT BY AN ADAPTATION OF RAMMSTEDT'S TECHNIQUE*

BY SAMUEL N. VOSE, M.D.†

IN a recent issue of the *Urologic and Cutaneous Review* (October, 1933), Dr. David M. Davis reports a case in which he employed in the treatment of ureteral stricture associated with calculus and perireteral abscess, a technique based upon the principle underlying the Rammstedt operation for pylorospasm. A review of the literature indicates that he is the first to report a case in which such a method has been adapted to obstruction in the urinary tract. It is interesting that, in the two cases which are here reported, a similar procedure based on the same principle was applied for the relief of hydronephrosis due to subepithelial fibrosis at the ureteropelvic junction.

CASE REPORTS

CASE I. a white male, aged 22 was admitted to the Urological Service of the Massachusetts Memorial Hospitals on February 17, 1931 for 24 hours' observation and on March 16, 1931 for operation.

Chief Complaint. Frequency of urination.

Family and Past History. Not remarkable excepting gonorrhea eight months previously for which he was treated in the Out Patient Clinic. Urethral and prostatic smears were negative for pus and organisms on several occasions after November 22, 1930.

Present Illness. The present complaint has existed for several months and has been accompanied by intermittent pain in the right loin. Urinalysis on three occasions prior to admission showed microscopic hematuria and the patient was referred to the hospital for complete urological investigation.

On admission regional examination revealed no significant abnormalities. The abdominal examination showed no tenderness at any point. Neither kidney palpable. External genitalia normal. Urinalysis: Specific Gravity 1.027. No albumen, sugar or acetone. Sediment showed a rare pus cell and no blood. Blood Examination: Leucocytes 9,600 per cubic mm., hemoglobin 80%. N. P. N. 30 and Sugar 74 mgm. per 100 cc. of blood. Wassermann and Kahn tests negative.

Cystoscopy. February 17, 1931. A large caliber stricture was found in the bulbous urethra. Bladder capacity and tolerance were normal. No irregularities of the bladder neck. Slight inflammation of the trigone. Ureteral orifices normal. No obstruction to the passage of a No. 5 ureteral catheter to each kidney pelvis. Stasis of 3 cc. on the right side and 7 cc. on the left. Divided function (P. S. P.) test showed 3 per cent on the right side and 2 per cent on the left in 15 minutes. Pyelogram of the left side was unsatisfactory owing to incomplete filling but was checked later by intravenous pyelograms. No definite pathology was demonstrated in the left kidney. The right pyelogram showed some dilatation of the pelvis and calyces with a narrow

ing at the ureteropelvic junction (fig. 1A). Urine from the bladder and each kidney was negative for pus or organisms and culture showed no growth.

Operation. March 18, 1931. The right kidney and upper ureter were exposed by the usual loin incision. Rather more than normal adhesions were found around the kidney pelvis and ureter. A definite narrowing existed at the ureteropelvic junction which seemed to be due to a narrow area of fibrosis in the ureteral wall and surrounding the ureter. It seemed that the division of this fibrous band without incising the mucosa, as in the classical operations, might relieve the stenosis. A longitudinal in-

FIGURE 1A.

cision one-half inch long was made in the wall of the ureter down to but not through the mucosa and as the edges drew apart, the mucosa could be seen bulging into the incision. After this incision was made the width of the ureter at this point became practically the same as that of the ureter below. Neither ureter nor pelvis was opened. The operative wound was closed without drainage. Convalescence was uneventful and the wound firmly healed on April 2. On April 3, the ureter was dilated with bougies and the patient was discharged from the hospital on the sixteenth postoperative day. He still had some frequency, but was relieved of pain in the loin.

Ureteral bougies were passed on August 18 and again on October 20, 1931. At this time 6 cc. of urine free from pus or organisms was aspirated from the right kidney pelvis. A pyelogram was made (fig. 1B). The patient stated that he was free from symptoms and failed to report for further check-up.

Comment. It is difficult to evaluate the importance of the operation in the relief of the patient's

*From the Department of Genito-Urinary Surgery, Massachusetts Memorial Hospitals.

†Vose, Samuel N.—Assistant Professor of Genito-Urinary Surgery, Boston University School of Medicine. For record and address of author see *This Week's Issue*, page 817.

symptoms, as the frequency and microscopic hematuria may well have been caused by the pathology in the lower urinary tract, and the pain in the loin might have been relieved by freeing the adhesions around the kidney. The principal evidence of the efficacy of the procedure employed is the altered appearance of the ureteropelvic junction as shown in the pyelograms.

CASE II, a white male, aged 17, was admitted to the Urological Service of the Massachusetts Memorial Hospitals on September 6, 1932.

Chief Complaint Pain in the left loin and left upper quadrant.

FIGURE I B

Family and Past History Not significant.

Present Illness Began about one year previously with a dull aching pain below the left costal margin. Attacks of pain have been intermittent, recurring at monthly intervals and lasting several days. The pain has been severe enough to require morphine. There have been no associated gastrointestinal or genitourinary disturbances.

On admission, regional examination reveals no significant pathology. Abdomen soft and pliable. Slight tenderness in the left upper quadrant and in the left loin. External genitalia normal. Urinalysis: Specific Gravity 1.009, no albumen, sugar or acetone. Sediment showed no abnormal elements. Blood examination: Leucocytes 8900, hemoglobin 80%, N.P.N. 32 and sugar 74 mgm per 100 cc., Wassermann and Kahn tests negative.

Cystoscopy September 10, 1932. Bladder capacity and tolerance normal. Bladder mucosa was normal throughout as were the ureteral orifices. A No. 5 catheter was passed to the right kidney pelvis without obstruction. Two cc of clear urine aspirated. A No. 4 catheter was passed up the left ureter to the kidney pelvis and 200 cc of clear urine aspirated. Pyelograms were made. On the right side there was slight dilatation of the kidney pelvis with normal calyces. The kidney was low and there was a kink in the upper ureter. The left pyelogram is shown in figure II A, a large hydronephrosis and the ureter not dilated below.

In view of the possibility of a nephrectomy being necessary on the left side, it was considered advisable to do a nephropexy on the right side. This was performed on September 13, 1932. Little pathology was found at this operation.

Operation September 30, 1932. Under spinal novocain anesthesia, the left kidney and upper ureter were exposed by the usual loin incision. Examination of the kidney showed considerable apparently healthy kidney tissue. The pelvis was greatly dilated. The upper ureter was attached to the kidney pelvis by fascial bands and across the lower part of the pelvis but well away from the ureteropelvic junction and the ureter was an aberrant blood vessel. This apparently was not a factor in the obstruction. The ureter was freed from the pelvis by dividing the fascial bands. At the junction of the pelvis and ureter was found a narrowing due to an area of fibrous tissue surrounding the ureter. The pelvis was incised and the fluid evacuated. A bougie was passed down the ureter with some difficulty. On withdrawal it was firmly grasped by the ureter at the narrow portion. A longitudinal incision about 3/8" long was made in the wall of the ureter through the fibrous area and down to but not through the mucosa following which a No. 12 soft rubber catheter could be easily passed down into the ureter. The redundant wall of the pelvis was resected by the removal of an elliptical section from the inferior surface the incisions starting about 1/4" above the ureteropelvic junction and extending nearly up to the kidney substance. The open end of the rubber catheter which had been

FIGURE II A.

passed down the ureter was brought out through a nephrostomy opening for constant drainage of the pelvis. The cut edges of the pelvic wall were approximated by two layers of O chromic catgut. The perirenal area was drained by rubber tissue and the operative wound closed by layer sutures.

Convalescence was uneventful. The catheter which served as a nephrostomy tube as well as a splint for the ureter was removed on the fourteenth postoperative day and for 48 hours there was slight leakage of urine through the sinns after which it remained dry. The patient was discharged on the twentieth postoperative day with both wounds firmly healed voiding normally and free from pain.

He returned to the hospital for dilatation at intervals of several months and on April 14, 1933, ureter catheterization revealed in the left kidney pelvis a residuum of 10 cc of clear urine free from pus and organisms. He had been free from all symptoms and had gained 25 pounds in weight since his operation.

FIGURE II B

On October 21, 1933, about one year after operation, the left ureter was dilated by bougies and a residuum of 15 cc of clear urine found in the left kidney pelvis. Indigo carmine injected intravenously appeared on each side in good concentration in five minutes. A pyelogram made on that date is shown in figure II B. The patient continues to be free from all symptoms.

Certain experimental work, notably that of Hinman¹, has tended to cast some doubt upon

the advisability of attempting conservative operations in cases of unilateral hydronephrosis. The results in the second case reported are in line with an increasing amount of clinical evidence indicating that considerable functional regeneration may be expected even in well advanced cases *provided the obstruction be completely relieved*.

There is considerable difference of opinion as to the relative importance of several etiological factors in the causation of so-called primary hydronephrosis. Disregarding the secondary effects of anemia and infection, and considering only the primary obstruction, there appear to be good reasons for agreeing with Geraghty and Frontz² that many cases originate from inflammatory processes in the ureteral wall, and that in certain instances, at least, kinks, abnormal implantations and obstructing blood vessels may be secondary to the distorted anatomy resulting from dilatation of the pelvis. Walters³, however, places subepithelial fibrosis third in a list of causes of obstruction. Whether the obstruction be congenital or acquired (inflammatory), there exist certain cases in which the mucous membrane is little, if any, affected. In such cases, an extramucosal division of the fibrous constriction, combined or not with such measures as resection of the renal pelvis or nephrostomy, as indicated in the individual case, may result in the complete relief of the obstruction so essential to the success of conservative operations.

LOCAL ANESTHESIA IN OBSTETRICS

BY CORNELIUS T O'CONNOR, M.D.*

ARTHUR Hertzler¹ remarks, "Many of the current writings on local anesthesia bear very obviously, the mark of having undergone a new experience, which they are anxious to proclaim to the world. It reminds one of the young swain who first kisses his sweetheart in the moonlight. He thinks he has discovered something new and wholly new. He has and he hasn't, it depends on the point of view." Having followed the literature on the subject of local anesthesia in obstetrics, having read the standard texts and monographs and having talked with colleagues as to the methods of anesthesia used by them, the writer is well aware that he has no new method, but he feels also

that there is a definite field in obstetrics for its use and that it deserves more consideration than is given it. The use of various drugs particularly the barbiturate preparations, has been exhaustively, even exhaustingly discussed in the literature.

Spinal anesthesia has been the subject of many papers, and of course the tetrad of general anesthetics, ether, chloroform, ethylene and nitrous oxid have been dealt with adequately. But when the subject of infiltration or nerve block local anesthesia is considered there seems to be both apathy on the part of obstetricians in their daily practice, and a paucity of articles in the literature. J W Williams in his text in the sixth edition states that he has had no experience with the method. He says that Gellhorn

*O'Connor, Cornelius T.—Visiting Gynecologist, St. Elizabeth's Hospital, Brighton. For record and address of author see *This Week's Issue* page 817.

is enthusiastic concerning its use in the second stage of labor in conjunction with "twilight sleep" According to Williams Gellhorn's method is direct infiltration of the perineum and the levator muscles with one half of one per cent novocaine solution The text of Shears Jellet and Madill, and Solomon's revision of Tweedy's manual contain no reference to the use of novocaine or similar preparations in normal or forceps delivery Joseph L Baer says in speaking of the conduct of normal labor, "Infiltration anesthesia of the cervix and perineal body has not won general approbation and is not to be recommended" Ralph M. Tovell³ says, "Sacral block is to be generally preferred over less precise and less satisfactory methods such as infiltration of the perineum or nerve block of the inferior pudendal and inferior hemorrhoidal nerve" By sacral block he means sacral anesthesia injecting about one ounce of one per cent novocaine solution through the sacral hiatus plus transsacral (sacral foramina) injection J B DeLee alone, is enthusiastic about the use of local anesthesia In the sixth edition of his textbook he says, "Wherever in obstetrics as in surgery, it is possible to operate under a local novocaine infiltration or nerve blocking this should be done since unquestionably the dangers are more than halved by the avoidance of general anesthesia In the Chicago Lying-In Hospital, in the home service of the Chicago Maternity Center, central episiotomy and repairs are usually done under 'local'"

In 1916, Robert W King⁴ in an excellent paper to which little attention seems to have been paid, said "While marked advancement has been made in the realm of anesthesia as applied to the local and general blocking of the sensory nerves of various parts of the body, it is strange that so little attention has been paid to applying these methods in the sensory innervation of the female perineum The literature of this subject is remarkable because of its scarcity, the subject apparently has not engaged the attention of American investigators and practically the only work of importance that has come to my notice, has been carried on in Germany" After carefully working out the anatomy and nerve supply of this region, King reported his results in nearly one hundred injections His conclusions were that lacerations were diminished, that anesthesia began in a few minutes and lasted for two to four hours, that repair was greatly facilitated, and that the general practitioner can safely and easily apply the method at the bedside

D Rose⁵ proposed a nerve block of the abdomen for relief of pain during the first stage of labor and direct infiltration of the perineum for the second stage of labor He was particularly interested in the use of novocaine for the first stage of labor Abdominal nerve block is

unnecessary, as various safe drugs exist for the production of analgesia during the first stage of labor He infiltrated the perineum and labia instead of doing a block of the perineal nerve

T Torland⁶ states that he has used local anesthesia of the perineum, for the past eight years in practically all primiparae and many multiparae, using a perineal nerve block He has injected novocaine in several hundred cases without complications or untoward results Some form of twilight sleep was used during the first stage of labor He feels that ether or gas anesthesia can usually be reduced to a minimum and can frequently be omitted In conclusion he states "When to this can be added the absolute assurance that this perineal anesthesia has no remote results, has no influence on the uterine contraction has no higher incidence of infection and no difference in wound healing, and that it can without much experience be used by anyone in the home as well as in hospitals it seems that we have here a method of considerable importance which merits further investigation and more extensive use"

DeLee⁷ unqualifiedly supports this view

M Oku⁸ used local anesthesia in one hundred cases He believes that there are no contraindications to this form of anesthesia except for purulent inflammation at the points of injection and their neighborhood He believes that the procedure is simple and harmless, that it removes all pain relaxes the muscles that the second stage is often shortened, that the number of episiotomies and lacerations is diminished, that forceps operations and breech extractions may be done under this anesthesia and finally that no disturbance in the labor pains, the separation of the placenta or the contractions of the uterus was observed

Abdurel⁹ uses nupercaine (percaine) He believes that it produces a more prolonged anesthesia than does novocaine A Reist¹⁰ does a pudendal nerve block using nupercaine "Ciba" (one to two thousand), using about 50 cc for each pudendal nerve Of thirty cases, the anesthesia was very good in twenty-seven and partial in three He prefers nupercaine to novocaine because the anesthesia in the case of the former lasted as long as six hours and nearly always four hours J P Greenhill¹¹ uses infiltration anesthesia for spontaneous and low forceps deliveries His technique is as follows,

"the needle is inserted about midway down one labrum majus and the solution is injected all along the edge of the labium then across the fourchette and up the edge of the other labrum majus It is usually necessary to remove and reinsert the needle a few times, but one must always reinsert the needle in an area which has already been infiltrated With Allis forceps, slight traction is then made on the infiltrated fourchette and solution is injected in the layer between the vaginal wall and the rectum not only in the midline, but also well out

to the sides in the shape of a fan. The needle is inserted about 6 cm in each direction and about 30 cc of the solution is distributed in this space. Then the needle is inserted deeply through the fascia over one levator ani muscle and about 10 cc of the solution is injected into the muscle and the fascia. This is repeated on the other side. Within a few minutes, examination will reveal relaxation of the entire perineal floor and gaping of the vaginal outlet. Because of this, the patients do not experience the forcible stretching of the perineum which most primiparae do. The second stage is shortened if there is no interference with the uterine contractions. The head passes through the outlet without any pain. If there is breech presentation, spontaneous delivery may be accomplished or manual aid rendered with little discomfort. In some cases labor pains slow down after the infiltration and it is necessary to apply low forceps or give two or three minims of pituitary extract. Perineal lacerations are reduced in number and size and there is less need for episiotomy. If a laceration occurs it may readily be sutured without the addition of any anesthetic.

There is then a striking unanimity of opinion as to the advantages of local anesthesia in obstetrics, among those who have used the method. What then is the reason for the indifference of obstetricians to the use of local anesthesia? It is possible that the explanation lies in the following: (1) Some surgeons will never be interested in local anesthesia, nor will ever use it successfully because they are temperamentally not adapted to its use. Deliberation, anatomical knowledge, patience, and frequently gentleness, are often required. (2) Many obstetricians have not been interested in its use because they have not realized that excellent muscular relaxation will be produced if a successful nerve block has been done. (3) Possibly when local anesthesia is mentioned, in many obstetricians the mental phantasm arises of a massive infiltration of the levators and the perineal body rather than a more precise nerve block of the pudendal nerve. (4) The knowledge that very apprehensive individuals are not good subjects for local anesthesia. It is to be remembered that, with the use of the various sedatives and hypnotics in the first stage of labor, this is no longer a factor. (5) A fear of a reaction from the amount of novocaine used. There need be no reaction if any of the barbiturate preparations are used before the injection. (6) Possibly a persistence of the old notion that pregnant women tolerate general anesthesia very well. J. T. Wallace¹¹ found on the obstetrical service of the Brooklyn Hospital during 1932 three cases of intrapartum and postpartum collapse due to aspiration during or following ether anesthesia. The writer recently had a case of alarming symptoms due to inhalation of vomitus following ether. It is probable that every obstetrician has had experiences such as these. DeLee¹²

says, "The longer one's experience grows the more one respects the dangers of general anesthesia."

The writer has used local anesthesia on primiparae for the past four years and uses the following technic. Ampules containing 5 cc of twenty per cent novocaine (Metz) are used. Dilution to 100 cc with normal saline makes a one per cent solution, to 150 cc makes a two thirds per cent solution. Either of these strengths seems to be satisfactory, more so than a one half per cent solution. With a sterile medicine dropper fifteen drops of one to one thousand adrenalin solution are added. This is essential. So great is the blood supply of this area that the anesthesia will be quite evanescent unless the adrenalin is used. Moreover an injection of a few cc of the adrenalized novocaine solution makes an episiotomy often bloodless. These 20 ampules are simpler to use than the tablets which must be crushed before use. Referring to the use of tablets which have incorporated in them epinephrine, Hertzler¹ says, "These are not always stable and it is best to employ the epinephrine solutions." Any type of syringe may be used successfully for the injection. The writer uses a Dunn syringe which is a two-way syringe of 3 cc caliber. With this type of syringe it is not necessary to refill. About 5 to 10 cc are injected into the spot where the episiotomy is contemplated. The ischial tuberosity is palpated. Fifty to 70 cc of one per cent or two thirds per cent novocaine solution are injected about one centimeter medially and caudally to the ischial tuberosity, at a depth of about 7.5 cm. If a two way syringe is used, it is kept moving slightly so as not to inject into a vein. If a large syringe is used, aspirate first to be sure that the needle is not in a vein. Use a needle which will bend but not break. The needle ought to be about 10 cm in length. In thin women 50 to 60 cc on each side is sufficient. In stout women 60 to 70 cc on each side should be used. About 5 cc is then injected in each labium majus and about 10 cc on each side of the sphincter and about 3 cm in depth. In a successful injection the relaxation is as complete for the outlet as it is under a surgical anesthesia. (See illustrations 1, 2, & 3.) The percentage of successful injections will vary. After it has been used by an individual twenty-five or thirty times, the nerve block is perfect in nearly every case in thin or normal women. In stout patients it has been the writer's observation that occasional partial failures result. Even in these, the amount of general anesthesia required is less and this is advantageous. For the normal delivery one of the barbiturate preparations plus scopolamine is used during the first stage. Occasionally a small (forty-five milligram per kilo) dose of avertin is used in the second stage. This or gas oxygen is valuable in the type of patient who is very restless under drugs of the barbiturate series. The

writer hesitates to use more than 45 mg in addition to drugs of the barbiturate series which have been used previously. For midforceps operations gas oxygen is necessary, as the blades pass into unanesthetized areas. This is no objection, however, as the writer has noticed on two occasions doing midforceps, that involuntary pushing of the patient when traction was made on the forceps, appreciably helped in the descent of the head. The amount of gas as re-

ILLUSTRATION 1

Block of perineal nerve. About 10 cc have been injected into site of proposed medio-lateral episiotomy. Gas oxygen administered until injection is done. This requires 2 or 3 minutes.

ILLUSTRATION 2

Delivery. No general anesthetic is being administered. Baby's weight 7 pounds. Patient is a primipara.

ILLUSTRATION 3

Repair of episiotomy. Bleeding from separating placenta. Clear cut avascular tissues due to adrenalin. No general anesthetic is being administered.

lated to the percentage of oxygen is less than when novocaine is not used. It is never necessary to produce even the slightest cyanosis to get results. As soon as the head is on the pelvic floor, gas oxygen may be omitted. Where the patient is very restless under the use of hypnotics such as sodium amytal, phenobarbital sodium, pentobarbital sodium, dial, sodium alurate etc., the use of gas oxygen (50 per cent gas, 50 per cent oxygen) is necessary until delivery is completed. In this case a small dose of avertin may also be used rather than the gas oxygen. Manual aid to breech delivery requires only local anesthesia, or at the most local plus 50 per cent gas 50 per cent oxygen. In the decomposition and extraction of a breech, however, fol-

lowing the technic of Irving and Goethals¹³ and Piper¹⁴ it is necessary to use ether or avertin in order to get relaxation of the lower segment of the uterus. Local anesthesia in addition will give the following advantages: 1 Routinely perfect relaxation of the outlet. 2 Less bleeding from the episiotomy which is now a routine in breech extraction. 3 Often a smaller episiotomy than with ether alone. 4 The use of less ether because the episiotomy may be sewed up under the action of the local, the ether being withdrawn as soon as the baby's head is on the perineum. The writer feels that the same advantage applies to the use of novocaine in the performance of version and extraction. There have been no reactions in over seventy-five private cases and there has been no infection in the areas injected. A consideration of the tremendous blood supply of the parts will bring the realization that infection should be indeed a rarity. Neither more nor less episiotomies should be infected whether done under a general or local anesthetic. Anesthesia produced with novocaine lasts three-quarters of an hour to an hour. It may last longer, but this duration can be depended upon. As noted previously, Abdurel⁹ and Reist¹⁰ state that they obtain an anesthesia lasting for four or five hours with one to one thousand or one to two thousand nupercaine solution.

Three other methods of using novocaine in obstetrics should be considered. 1 Caudal anesthesia. J W Kelso¹⁵ used it in thirty-four cases. He felt it had the following drawbacks: (1) It must be given only under the strictest precautions and cannot therefore be used in the average home delivery. (2) The administration is technically not easy, it is not always possible to gain entrance to the hiatus. (3) He felt that this anesthesia produced a certain amount of inertia in practically every case. In a personal case the insertion of the needle into the hiatus resulted in the presence of spinal fluid, necessitating the withdrawal of the needle, as the doses used for this anesthesia would almost certainly have produced serious consequences if injected into the spinal canal. The method of sacral block which was preferred by Tovell³ to perineal nerve block, consists in a caudal anesthesia plus injection of each sacral nerve, gaining entrance to the foramina posteriorly. The writer has not used this method. It would seem open to the same objection as caudal anesthesia plus the fact that more time is consumed in the injection of the sacral nerves individually. Moreover from Tovell's description the procedure would not seem to be easy technically. The third method of using novocaine is that of spinal anesthesia. M F Eades¹⁶ used this method in one hundred and twenty-one cases. They were all, however abdominal obstetrical operations. His conclusions were

that it had a definite place in abdominal obstetrical surgery when the use of general inhalation anesthesia was contraindicated, but that the method was safe only with a judicious selection of risks and careful technique of induction, and a close observation of the patient during anesthesia and preparedness for any unfavorable reaction. He felt that it was contraindicated in bad risks or when shock or hemorrhage was present. The dosage used by him was 200 mg. In normal deliveries or in low forceps operations or breech extractions, a smaller dose than this would be quite sufficient. Not over 100 mg should be necessary and 75 should suffice for normal or low forceps cases. Eades¹⁷ feels that a dose of 75 to 100 mg of novocaine crystals is perfectly safe. Further experience may show that in well-equipped hospitals spinal anesthesia in doses of 75 to 100 mg may have definite advantages in some cases over nerve block of the perineum.

SUMMARY

1. The technique of the use of local anesthesia for normal and low forceps deliveries by infiltration of the perineum, and by block of the pudendal nerve is described.

2. The method is simple and safe. The criticism that it is a "hit or miss" method is true of any nerve block. The greater one's experience the fewer the "misses." Its use is suggested for the termination of labor in those patients for whom a general anesthetic is contra-

indicated. It is particularly suggested in toxemic patients.

3. Its use is also suggested in addition to a general anesthetic in breech extraction in primiparae, and following versions. A successful nerve block produces excellent relaxation of the outlet, a condition postulated by Potter, as a cardinal prerequisite for a successful extraction.

4. Where a general anesthetic is necessary it will reduce the amount needed.

RIGID FLAT FOOT—REMODELLING

BY FREDERIC JAY COTTON, M D,* AND GORDON MACKAY MORRISON, M D*

THERE is nothing new about the recognition of flat feet of long standing that have become utterly rigid, so far as tarsal flexibility goes. Nothing new about forcible remodelling of selected cases of this sort. There is, however, something to say about choice of cases and there is something to say about an instrument (most simple) to which we have no claim save that of adoption, that helps a great deal. There is something to say about the ultimate remodeling, in the plaster boot, and something also about the *physiology* of recovery of function and proper stance. As to choice of cases, there is no use in attempting simple mobilization in feet in which years of growth with distorted bone relations have resulted in considerable change in the bony "architecture." Any successful remodelling of such feet must include remodelling of bone. Only feet rigid from spasm and con-

tracture with decently normal bone shapes are fit for manipulation remodelling.

As to the instrument (fig 1) it is a very simple "strap wrench" devised by the late Dr Gwilym G Davis of Philadelphia. It is of 3/8" tool steel of good quality welded and tempered, or the apparatus will buckle up under use. The straps A & B are simply buckle straps of 1" or 1 1/4" webbing. The whole instrument is about 18" long. Only the straps come in contact with the skin and do not bruise even under heavy leverage.

Its original use was for stretching a tight tendon Achilles*, but it is most serviceable where one needs more force than that of the bare hand for correction in any direction, and much force is usually needed, for, in order to attain correction one must first *overcorrect* these deformed feet. Otherwise, the tension of the plaster to maintain position is unbearable. It is not the violence of the reduction, but the stretching of *untorn* tissues that gives pain. If this is re-

*And properly used for this it renders the once fashionable operative lengthening of heel cords a rare operation.

membered such corrections do not give great postoperative pain

As to the ultimate remodelling, one point not perhaps quite easy to make clear is of para-

FIGURE 1 The Davis strap wrench

The essentials are the hairpin shaped lever and the two webbing straps through which leverage is exerted on the foot in the desired direction. The short bow simply braces the long rods apart. Otherwise under the heavy strain they would bend inward.

mount importance. If we correct the whole foot inward into varus position as in A of figure 2, then when the plaster comes off the *front part* of the foot must needs come back to the flat surface and in so doing is at least as likely to swing the whole foot (heel included) at the subastragaloid joint as at the mediotarsal level. That, if it happens pretty much spoils our correction. If however, the foot is corrected into varus, the heel then held in sharp varus (see

B) while the front part of the foot is brought back to neutral position, then this recurrence of deformity does not happen. This can be done though it calls for good plaster work.

FIGURE 2 A. The usual position in which a remodeled flat foot is apt to be put up. Unfortunately in this position the mediotarsal joint stiffens somewhat and when the sole comes flat it is very doubtful which joint will go back into eversion.

FIGURE 2 B. The proper position. The foot is put up in plaster with the heel just as sharply inverted but with the front part of the foot already rotated at the mediotarsal joint to the position of the normal tread.

If this is done, then a few weeks of exercises, and the wearing of the efficient (if not too comfortable) Whitman "rocker" plates, are apt to be followed by gratifying results.

It is recognized that this handling is heresy—that is to say it is not what is taught but it is sound physiological mechanics,—and it works.

A SEPARATE OSSIFICATION CENTRE FOR THE INTERNAL MALLEOLUS

BY ALEXANDER P. AITKEN, M.D.*

MUCH has been written about the "Occasional Epiphyses and the So-Called Additional Bones of the Foot." Notable among these are the os trigonum and the epiphysis at the base of the fifth metatarsal. However in all the literature we have been able to find but one reference to the condition which we are about to describe. Poland in his classical work "Traumatic Separation of the Epiphysis" quotes a case of Beclard, as follows:

"Beclard has once seen and described a special centre for the internal malleolus immediately joining the principal portion, but the author has never seen a distinct epiphysis and its occurrence must be extremely rare."

The internal malleolus usually develops along with the distal articulating portion of the tibia from the distal epiphysis, the development of the internal malleolus occurring as a downward growth from the inner side of the epiphysis. Up to the sixth year no definite internal malleolus can be seen by x-ray, however a definite downward growth does begin about this

time (Cohn). At about eight and a half years a definite downward projection is noted on the inner side of the epiphysis. From the tenth to the eleventh year, a definite internal malleolus is formed. By the fourteenth year there is usually a complete ossification of the epiphysis of the tibia, although the epiphysal line is still present. This line does not disappear until about the sixteenth year (Cohn).

The following case is interesting in that it shows that the internal malleolus need not develop as above but from an ossification centre of its own. Also, when this condition does exist, it might well be mistaken for a fracture.

CASE. H. H. aged ten years. Admitted to the Chelsea Memorial Hospital with a history of having had his left foot caught in the rear wheel of an automobile. The left ankle was swollen and there were two lacerations over the lateral aspect of the lower leg and ankle. There was considerable tenderness over the external malleolus. X-rays were taken for a questionable fracture of the fibula. These revealed a definite crack through the internal malleolus which was interpreted at first as a fracture. However closer inspection of the dry plates revealed the fact that the fractured edges were lined with a very fine layer of cortical bone. This brought up the question as to whether this was not actually an ab-

*Aitken, Alexander P.—Assistant in Surgery, Boston City Hospital. For record and address of author see *This Week's Issue*, page 51.

Tracings of roentgenograms of the normal ankle at various ages showing the usual development of the internal malleolus

normal epiphysis. An x-ray was then taken of the opposite uninjured ankle, and a similar picture found in the internal malleolus, giving conclusive proof that we were dealing with an abnormal epiphysis.

According to the literature, or rather to the absence of literature, it would seem that this condition is exceedingly rare. However, it is possible that if all fractures of the internal malleolus were more carefully examined, especially for the presence of a thin cortical layer, as one sees in the os trigonum, perhaps this condition is not actually so rare as it might seem.

THE ADDRESS OF DR. STEPHEN RUSHMORE
AT THE HEARING ON HOUSE BILL 118*

HOUSE Bill 118 has been presented in accordance with Chapter 112, Section 4 and Chapter 30 Section 33 of the General Laws, having been drafted by Counsel for the House and is part of the Annual Report of the Board of Registration in Medicine. By vote of the Board, the Secretary has been only authorized to make representations for it and much of what is submitted to this Legislative Committee is an amplification of material already incorporated in the Report but not yet published.

The object of the Bill is to give increased protection to the health of the people of Massachusetts by raising the qualifications for the practice of medicine. The recommendations of the Board concern several minor modifications of detail, and one important change in procedure which is to give the Board power of approval of medical schools from which it receives candidates for examination.

In the recommendations of the Board, which accompany the Bill, there are discussed adequately, I think, all of the minor changes suggested, and they will need no amplification at this time, although I shall be glad to answer questions about them if the Committee desires. I shall discuss briefly the important change concerning approval of medical schools, which is the feature of most significance from the point of view of protecting the public.

Before discussing the new bill, I would like to say a few words about a noteworthy change in the medical practice act made in 1933. The provision to which I refer is the requiring of the candidate that he spend four years of not less than thirty-two weeks in each year in some medical school. The significance lies in the fact that for the first time in the history of medical legislation in Massachusetts, attention has been paid to formal medical education as a qualification for practice. The requirement as worded is not severe, but the direction in which it carries the statute is absolutely new, and is in the line of progress. The requirement is not that the candidate shall take certain courses and complete them in a manner satisfactory to the school, not that he shall advance from year to year in a graded medical course, but merely that he shall live through four years of attendance in a medical school. It does not represent a very high standard but it is better than the statute before the amendment of 1933.

The object of the new bill is to raise the qualifications for the practice of medicine in Massachusetts. Are the qualifications not high enough already? From the point of view of the

person who is ill, the qualifications cannot be too high, we would like every patient to have the best that the science and the art of medicine can give. That is ideal, but the statute cannot deal with ideal conditions, it can establish only reasonably high minimum standards of qualification below which it is not safe for the patient to permit the physician to fall.

What are reasonably high standards? May I say again that ideal standards would be unreasonably high to incorporate in the statute, and that reasonable refers to the standards of the community. In New England Massachusetts has the lowest statutory standards, in spite of the excellence of many individual practitioners of medicine, and the excellence of some of its medical schools. In fact, Massachusetts has the lowest statutory standards in the whole United States. To many persons, proud of the traditions of Massachusetts for enlightened legislation, the mere fact that, in this respect Massachusetts has the lowest standards would be sufficient reason for raising them to at least the level of the general average. Can there be any question that the standards should be raised at least to the general level prevailing throughout the United States, prevailing even in those parts of the country which we are sometimes accustomed to look upon as backward in protecting the health of their citizens?

The recommendation of the Board is that Massachusetts should adopt the requirement that has been adopted and found to be satisfactory in every other jurisdiction in the United States, and in fact has been adopted in Massachusetts for every other Board in the Division of Registration, whose registrants have to do with the bodies of living persons, namely, to give to the Board of Registration in Medicine discretionary power of approval of schools from which it accepts candidates for examination.

The first question that naturally arises is, why should medical schools need approval? Or to put it the other way, why should not every medical school be approved? The answer is that some medical schools are doing a very poor job in providing medical education. I shall show first why this is so, and, secondly, in what respects it is so.

The question may be asked, if some schools are doing such a poor job, why not let natural competition do its work? For students will not go to poor schools and thus the schools may disappear for lack of students. The answer lies in what the State is doing for these poor schools.

In general, there are two and only two statutory requirements in Massachusetts if a medical school is to be able to send its graduates up for examination by the Board. It must be legally chartered and it must be empowered to

Presented before the Committee on Public Health of the Massachusetts State Legislature April 3 1934

Rushmore Stephen—Secretary Massachusetts State Board of Registration in Medicine. For record and address of author see This Week's Issue page 817

confer degrees These requirements are distinct and definite, and it can be determined easily whether an institution does or does not fulfill them The state, in requiring the degree in medicine, has put a commercial value on the degree, and by refraining from any other requirement for the school, has left it free to do anything it sees fit in the way of giving a medical education There are no limits to the degradation of medical education that the school may choose for itself To be sure there are no upper limits set by the state beyond which a school may not go, but no one can make money giving an excellent medical education and it is possible to make money by giving a degraded medical education The state should interfere to prevent the degradation of the power which the state has conferred and the Board recommends that it should employ the procedure used by nearly every other jurisdiction for this purpose

In this discussion it will be convenient to use the classification of medical schools employed generally by state boards of registration in medicine, namely, some schools are approved and the others are not-approved

The records of the graduates of the not-approved schools indicate that these schools are not doing a very good job, and it is partly on the record of the graduates that the schools are not approved These graduates of the not-approved schools which are in Massachusetts are not admitted to examination for licensure in any jurisdiction in the United States except in Massachusetts The reasons for this are best known to the administrative boards of these jurisdictions, but I venture to suggest that if they all agree, there is probably some good reason for the agreement So Massachusetts stands alone, as opposed to all the other states, in its policies regarding standards of medical education

Justice Oliver Wendell Holmes, a distinguished son of Massachusetts, has said, "If I am in a minority of one, they send for a doctor or lock me up, and I am so far able to transcend the to me convincing testimony of my senses or my reason as to recognize that if I am alone, probably something is wrong with my works"

In the examination before the Board of Registration in Medicine in Massachusetts, the records of the graduates of the not-approved schools are clear, and I would refer only to the Report of the Board for 1932 There in table IV, one not-approved school shows a total of 75 per cent rejections, a second 65 per cent rejections, another 92.5 per cent rejections, 96 per cent, 80 per cent, 100 per cent rejections In the tabulation of rejected candidates (table V) one candidate from an approved American school was rejected twice, but registered on the third examination, and one candidate from a foreign school was rejected three times but registered on the fourth examination No other candidates from approved schools failed more

than once But from not-approved schools there were candidates examined 14, 19, 13, 11, 17, 11 and 17 times respectively and not yet registered Does any one think that these candidates bought reasonably good medical education?

Last year I called your attention to the number of complaints against physicians that had been made to the Board There were relatively five times as many against graduates of not-approved schools as against graduates of approved schools In the days of the "noble experiment", permits to prescribe alcohol medicinally were revoked in relatively five times as many cases of graduates of not-approved as of approved schools Surely there must be something wrong with the method of selection and the training given in the not-approved schools

It is not to be understood, of course, that the Board claims that every graduate of an approved school is qualified for practice The records of the Board and the records of the graduates in practice show that this is not so But the records of the Board and the records of the graduates in practice show also that there is an unreasonably high percentage of unqualified practitioners among the graduates of the not-approved schools It is because the not-approved schools, are, judging by the results, taking no proper steps to remedy this condition, that the Board asks the legislature to take action

I have here the catalogues of some of the not-approved schools, and I am going to let them speak for themselves, for I would like to have you realize, if possible, just what these schools are actually doing I shall not give complete descriptions of these schools but I can assure you that whatever I say of the schools is based on what I find in the catalogues, I do not guarantee that they speak the truth

I have written to the not-approved schools for their latest catalogues, but not all of the schools have replied, so that if I quote from catalogues which are not the latest you will understand why I do so I may say that mere writing for a catalogue does not ensure securing one Some months ago, I received a letter from an organization interested in suppressing improper advertising, asking if I found any improper advertising in the latest catalogue of one of these schools As the letter was not accompanied by a copy of the catalogue I requested one from the school but received no reply Later I wrote again, by registered mail, requesting a return receipt card In due season a letter came expressing regret that the school could not send me a catalogue, the supply was exhausted, and for reasons of economy it was doubtful whether more would be printed

I shall mention no school by name, because I desire to emphasize the principle of approval, and to indicate what is done by schools which are not controlled by discretionary approval of an authoritative body outside of themselves

One of the claims made for these schools is that they give an opportunity for the poor boy to study medicine. In most cases it is impossible to remove the handicap of poverty, but the burden can be lightened by intelligent effort. What effort is made in this direction by the not-approved schools?

One of these schools claims that it specializes in poor but worthy students. Let us see how it specializes. The thing that the poor but worthy student needs above all other things that he does not have is money—financial assistance. This school which specializes in poor students says that it can do little financially for them, and then to quote its own words exactly "perhaps it is better it cannot help in this way." Reading further, one finds no evidence that financially it does anything at all, although it acknowledges that it can do "little", and all that it actually does in any way, beyond talk about it, is as follows: "Students may stay out a year or more, and if deserving, will always find their places reserved for them." How difficult or easy it is for the school to make this effort and reserve places for the poor students, is shown by a reference to the capacity of the school, seventy-five in each class, and to the number of students enrolled, varying from fifty-two to sixty-two in the different classes. So that there are from thirteen to twenty-three vacancies in each class, which the school reserves by great effort, perhaps, as there is no demand for them.

There is one approved school of medicine which some of its friends speak of as one of the great medical schools of the United States, even of the world, which makes no pretense to specialize in poor boys. I am credibly informed that this school has about forty thousand dollars a year available for needy students in the form of loan funds or scholarships. The cost of tuition in the two not approved schools is three hundred and sixty dollars a year, and four hundred dollars a year in the approved schools. It would seem that if a school really specialized in poor students it ought to do something financially for them.

Then there is a not-approved school which says that "it recognizes the 'Mark Hopkins' element (in education) and its importance." It is hardly necessary to remind a Massachusetts audience of what this means, that Mark Hopkins was the eminent president of a small but distinguished Massachusetts college and that a president of the United States, James A. Garfield was drawn "irresistibly" to Williams College by a letter from President Hopkins. President Garfield said that his idea of a university was sitting on a log with Mark Hopkins. American education has been enriched by this noble tradition of the influence of a great teacher, which is the "Mark Hopkins element." Let us see what this not-approved medical school has done about it, besides recognizing it.

I have checked the whole list of the trustees and the faculty of this not-approved school against the list of members of the medical society of the state in which the school is situated.

Now the State Society is a constituent member of the American Medical Association which is the alleged "medical trust", described by some of the not-approved schools as trying to suppress them. So that even in the face of the alleged opposition by the "trust" I find that 28 out of 91 members of the faculty are actually members of the "trust."

Let us see how the trustees and faculty fare in some other lists with which not even these schools allege the trust has anything to do. There is first the list of members of the American College of Surgeons with a total membership of about ten thousand in the United States and over seven hundred in the state in which this school is situated. I find no name in this list of surgeons, and I would remind you that membership in the American College of Surgeons is not limited to graduates of schools which may be approved by the Regents of the College. Graduates of any medical school, if showing qualifications of achievement may become eligible.

Then I have checked the list of trustees and faculty against the directory of American Men of Science containing the names of over twenty-two thousand men and women in the United States who have attained distinction in science, research and education. Though there are many doctors of medicine found in this directory, there is no one from the faculty or trustees of this school.

I have checked this list finally against "Who's Who in America," which needs no description by me. Again I find no name from the list, so that while this school recognizes the "Mark Hopkins element" which goes beyond the medical profession, the "Mark Hopkins element", so far as I can determine does not recognize this school.

In one of the catalogues is the statement that the school is the only eclectic medical school in the United States. This statement is not true and was not true when the catalogue was published, but an egotistical error of the sort is easily forgiven. Elijah the Tishbite thought he was the only prophet in Israel, but he was gently but firmly reminded that there were seven thousand others. I find that this eclectic school devotes some space to a discussion of eclecticism. Now if one writes the word eclecticism with a small *e*, then every scientific physician is an eclectic, for it is his duty and his pride to use whatever means he can find from whatever source to help his patient. If one writes it with a capital *E*, then Eclecticism refers to a narrow sectarian school which is generally regarded as having outlived its usefulness. In spite of the fact that there is no evi-

dence in the outline of the course of studies in this school as given in the catalogue that the students are trained in Eclecticism, I find that they have been grounded so thoroughly in the principle of choosing what they think is best for their patients and themselves that when they were asked at the time of their application for examination before the Board what school of practice they plan to follow, of one hundred candidates, fifty-four or more than half chose the regular school of practice, twenty-one chose the Eclectic school of practice, twenty chose both regular and Eclectic, one chose Homeopathic and Eclectic, and four were apparently unable to make any choice at all

One finds here and there suggestions of intentional misrepresentation. For example, it is stated somewhere that although the students are admitted to advanced standing, that is at other points in the four year course than at the beginning, "it is understood", that because of the full enrollment there are comparatively few such students accepted. Referring to the capacity of the school and the number actually enrolled one sees that there were about twenty vacant places in each class so that one wonders who it is that understood that the enrollment was full. Certainly no one who read the catalogue was justified in any such understanding.

I would call your attention to the system of examination set forth in one of these catalogues. There are "student examinations" given every month. There are "faculty examinations" usually covering longer periods of instruction than the student examination. "These examination books may not be returned to the students". Then there are the "Trustee examinations" the books of which are graded by four persons "usually not connected with the college". By this system, you can see that control of the student is taken away from the faculty and transferred to four persons "usually not connected with the college", who may be controlled by the administration, perhaps one person. It is the set-up for a dictatorship.

Then I find in one of the catalogues the statement that although this school is not subject to the Council on Education of the American Medical Association and is not a member of the Association of American Medical Colleges, its admission requirements are equal to the requirements of either of these two organizations. The only thing to be said about this statement is that it is not true.

There are some amusing statements to be found in this rather dreary reading of the catalogues. For example, "In the interest of economy, this catalogue does not publish the usual uninteresting, encyclopedic and redundant descriptions of courses of study, prefaced with long lists of professors. These courses are practically the same in all medical schools including" the school making this statement and "Anyone de-

siring such a description should consult any one of the usual conventional catalogues". Gilbert and Sullivan hardly did anything better than that.

One of the schools advertises what is in substance the set-up of a diploma mill. Of course, the old-fashioned diploma mill, which sold its diploma after no course of study was pursued by the candidate, is gone. But this school to which I am referring admits "to advanced standing", this does not mean postgraduate work, physicians registered in the state in which the school is situated. Then we find that one of the conditions for receiving the degree of doctor of medicine is a hospital internship or *its equivalent in practice*. Translated into plain English this means that an osteopath, if he is registered to practice medicine in the state in which this school is situated, may be admitted to advanced standing, and after fulfilling requirements that are very vague, may go back to his office and practice medicine, and in due time receive a diploma indicating that the degree of doctor of medicine has been conferred upon him. The catalogue says nothing definite of the cost to the candidate of the permission to practice while enrolled in the school or of the cost of enrollment in the school while practicing medicine but undoubtedly this is arranged through the usual channels. Now I have no evidence that diplomas are actually sold in this way. I am simply pointing out to you that this school publicly advertises the set-up of a diploma mill for the benefit of osteopaths, who are already registered by the Board. Since the candidate is duly registered, his license to practice is not involved by receiving later the degree of doctor of medicine in this way. In the days of the "noble experiment", if a man was found to have a still in his cellar he was condemned. I do not say that was just, but I am pointing out to you that a medical school advertises publicly that it has a diploma mill in its cellar which it can use.

What has the graduate of one of these not-approved schools received in return for the money he has paid, and how much money has he paid? The tuition fees vary, but one school to which I have already referred has a fee of \$360.00 a year. A graduate from this school has then bought for \$360.00 eligibility to examination in one state only, and a chance of passing that examination within the first year which is about fifty-fifty. For forty dollars a year more, or \$400.00, he could have bought in Massachusetts, at any one of three approved schools, eligibility, after a year's internship, to take the examination in any jurisdiction in the United States, and a practical certainty of passing that examination within one year. But that is not all. The graduate of a not-approved school, even if registered in Massachusetts, would find himself handicapped in getting a position in a good hospital, in getting work with

insurance companies, in getting protective insurance as a physician, in getting admission to medical societies. The graduates of these schools know these things perfectly well and that is why some of them, having had the bitter experience of this handicap for years desire that the schools from which they received their degrees become approved schools as it would so greatly improve their own standing in the community. I trust that some of these physicians will have the courage to tell you publicly what they have told me privately.

It has been said that these not-approved schools are meeting a demand and filling a need. I have already referred to the demand by the poor boy and I need say nothing further on that point, but there is another demand, namely, for more places in medical schools for persons who want to study medicine. But for just what is this demand? Is there any great demand for medical education in a not-approved school? Every not-approved school could admit more students than it now has, if more candidates applied. There is no not-approved school that selects its entering class from over a thousand candidates, and yet a number of the approved schools do just that. Last year there were 16,000 applicants for medical schools in the United States. Only 6,200 were admitted. There is not a single not-approved school that could not fill its class rooms to overflowing if only it became an approved school, yet thus they all refuse to do. Why, they perhaps will tell you.

What does this discretionary power of approval by the Board actually mean? Apparently it means very different things to different people. I have been reading of late some of the things written by persons opposed to the conferring on the Board of such discretionary power and they give a picture of a situation so different from the facts as I see them that I would like to take a moment to discuss this point.

For example, from what I have been reading I get the picture of a powerful Medical Trust which has, by various means on the whole rather underhanded, gained control of all the medical schools of the country except the not-approved schools. These they say, in a high spirit of independence refuse to be bound by the chains of the Trust. Furthermore, none of the approved schools is able to do anything except what the Trust permits, it is, so to speak, bound hand and foot. Does it sound reasonable that great universities some of them wealthy and powerful institutions, should have to do what the American Medical Association says? I remind you that this Association is called the Medical Trust.

The facts are in the first place, that the only thing that the American Medical Association can do to a school of which it does not approve, is to say that it does not approve, the expression now used by the Association is to say that

it does not recognize the institution. In the second place, these dreadful requirements that the Association makes are simply that the school shall not fall below certain generally recognized minimum requirements for a good medical education. It does not say a school shall not grow as high as it desires, nor as wide as it desires, but it says the school may not go down, may not degrade medical education. Each school determines for itself how excellent a school it may become within the limits of its resources but it cannot degrade medical education and be approved.

There are approved medical schools which, seeking to do the best they know how and to give as good as possible a preparation for the practice of medicine might be ashamed of themselves if they could do no better than attain the minimum requirements of the American Medical Association. The minimum requirements are to prevent dangerous degradation and to protect the public and for no other purpose.

What is the Board trying to accomplish by this proposed change in the statute? There has been much misrepresentation. Notwithstanding statements to the contrary, the Board is not trying to revoke the charter of any medical school, nor trying to have it revoked. The Board is not trying to close any medical school nor have it closed. There may be too many or too few medical schools in this country, or in Massachusetts. That is a question outside of the province of the Board. But if there were a thousand medical schools in this country, and if they degraded medical education beyond any point reached in the past or in the present, it would be a matter of comparative indifference to this Board if it had the power to perform adequately that function for which it was created, namely to protect the people of this Commonwealth against unqualified practitioners of medicine.

What is a qualified practitioner? The qualifications for the practice of medicine are four: morals, manners, knowledge and skill. On all of these points the candidate should be tested and yet on some of these points the candidate cannot be tested directly by the Board. How can the Board test morals? It must be satisfied with statements by other people and you can understand of how little value some of these statements may be. How can the Board test manners? Manners can be tested only when the candidate is actually practicing, is dealing with patients, when he is in action, so to speak. Only then can it be seen whether he is actuated by proper motives and shows proper consideration for the ill persons who entrust themselves to his care. Here also the Board cannot make any satisfactory test.

Knowledge it can and does test, but so vast is the field now covered by medicine that this test can be made only by samplings from some of the so-called major subjects.

Skill, the Board cannot test, as it is not possible under the present conditions for the Board to give a comprehensive practical examination

Nevertheless these qualifications can be tested and a system has been devised which is in active operation in many places and has been found to be reasonably satisfactory. It is an educational system, employed thoroughly in connection with some medical schools, and in part by nearly all of the others. There is the requirement of at least two years of preparation for the study of medicine in an approved college, then four years of study of medicine in an approved medical school, finally, at least one year of internship in an approved hospital. The critical point in the whole system is the raising of the question: Is this candidate qualified as to morals, manners, knowledge and skill to carry the responsibilities of a physician? If this question is raised again and again by the teachers throughout the course and is answered with intelligence and sincerity and honesty, then the Board may be justified in accepting testimony about those qualifications which it cannot test for itself.

But the point here is that not all medical schools are doing this testing thoroughly, and so if the Board is to accept the judgment of the school for any part of the testing, it should have discretion as to the school whose judgment it is to accept, that is to say, as to the school of which it does approve. This does not mean that the Board would give up at all its own responsibility or its own tests, it means that the

Board would be able to take advantage of the facilities of the school as it cannot do now.

I wish I might take the time to point out to you some of the changes which have taken place in medicine, in the past fifty years, what progress has been made in the acquiring of knowledge which must precede the application of knowledge in the relief of pain, in the prevention of disease, in curing disease, in prolonging life and in almost innumerable ways extending man's control over disease. Yellow fever has almost disappeared. We are protected from roads by the plague, cholera, smallpox which, until recently, took such a dreadful toll in death. Tuberculosis is diminishing. Even cancer now shows yearly an increasing number of cures. Surgery has become almost new, such marvelous progress has been made.

The qualified physician is one whose mind is flexible, adaptable enough to advance with the progress of his art. It requires knowledge, it requires training, it requires severe discipline to produce the skill even to find out what progress has been made. A man can keep abreast of the times in a small field only. But the qualified physician is one who knows how to make available to his patient what the science and the art of medicine are providing for the cure or amelioration of his illness and in many fields preventive medicine assures the individual and the community of freedom from the devastating effect of many diseases. All of these applications of medicine require well trained doctors who have recognized standing with their fellows.

SALYRGAN ITS LONG-CONTINUED USE IN CARDIAC INSUFFICIENCY WITH LATENT EDEMA

BY IRA M. DIXSON, M.D.*

THE bulk of the literature on the mercurial diuretics is to be found in the foreign journals, principally German. A number of articles have been written about salyrgan dealing with its chemistry, its behavior in the body and the mode of its action. Salyrgan directly affects the kidney and seems to produce diuresis primarily by depressing the cells of the tubular epithelium thereby hampering diffusion or reabsorption while filtration is little, if at all, affected. On the clinical side the indications for its use and application have been well studied and reported. Its toxic effects have been stressed from time to time. These are rare and seem to consist of mild renal, gastro-intestinal and skin irritations, although sudden death from salyrgan has been reported.^{1, 2}

A search of the literature through June, 1933, reveals that reassuring case reports of its long-

continued use are not numerous. In 1924 Bernheim³ reported a patient who had been treated for five months without irritative symptoms. Valette⁴ (1927) reported the use of novasurol for one year in a patient. Agnew⁵ (1928) reported a favorable result in a patient with portal cirrhosis who received 2 cc of the drug every other day for nine months. In 1932 Wiseman⁶ published a case report of an obese woman handicapped by decompensated hypertensive cardiovascular disease who, in 1925, at the age of 58, began receiving injections of novasurol and later salyrgan and progressed to a total of 270 injections before death supervened five years later. The diuretic response was gratifying throughout, with no harmful results on the kidney or other organs.

It is deemed of interest to bring to the attention of practitioners the following case report of a man who has received well in excess of 150 injections of salyrgan, intravenously, continu-

*Dixson, Ira M.—For record and address of author see "This Week's Issue" page 817.

ously for more than the past year and a half. It may be that salyrgan has preserved his delicate balance between compensation and decompensation and has enabled him to lead a reasonably useful and happy life meanwhile.

This is the story of a man in his seventy-third year who has lived a singularly vivid and useful life. For the past several years he has been under the care of Dr. Herman O. Mosenthal of New York, to whom I am indebted for the details of his past history and the privilege of publishing this case report.

testinal tract were carried out and found to be negative. The pains were relieved by nitroglycerine and the conclusion was reached that they were due to pathology in the coronary arteries. In September, 1930 upon his return from a European trip, he complained of severe pains in his knees, shoulders and neck. A week or two later he was forced to bed because of fever and marked lassitude. The fever continued for several months and no definite conclusion as to its cause was ever reached despite thorough study. The only occurrence outside of the general malaise and fever was a left facial paralysis which came on very suddenly and disappeared in

The patient first came under observation in October of 1923. At that time he was found to be of approximately normal weight, with slight thickening of the peripheral arteries, blood pressure 176/88, a systolic murmur over the whole precordium and a faint diastolic murmur over the sternum. The lungs showed no emphysema. Routine laboratory studies were essentially normal. It was concluded that this was an instance of aortic insufficiency on an arteriosclerotic basis and that the heart was compensating perfectly. In July, 1929, he became suddenly blind in his right eye due to an occlusion of the right central retinal artery. Both before and after this at rare intervals there were attacks of paroxysmal dyspnea and also in 1929 he began to experience occasional epigastric pains. These became severe in November 1929. X-ray studies of the gastro-

intestinal tract were carried out and found to be negative. The pains were relieved by nitroglycerine and the conclusion was reached that they were due to pathology in the coronary arteries. In September, 1930 upon his return from a European trip, he complained of severe pains in his knees, shoulders and neck. A week or two later he was forced to bed because of fever and marked lassitude. The fever continued for several months and no definite conclusion as to its cause was ever reached despite thorough study. The only occurrence outside of the general malaise and fever was a left facial paralysis which came on very suddenly and disappeared in the course of a few weeks. The only residue of the malady was the development of rather severe angina pectoris which was made distinctly worse by nervous tension and excitement. In April 1932 there was an attack of coronary thrombosis associated with marked cardiac insufficiency from which the recovery was very slow. Parenthetically, it is of interest that since this attack, the angina pectoris has practically disappeared. It was during his convalescence from this coronary episode that salyrgan was first used. For an interval during the summer of 1932 while traveling, its use was omitted and there soon resulted an alarming state of decompensation. Otherwise its use has been continuous. The accompanying chart graphically shows the diuretic response to salyrgan which has always been satisfactory. The natural gain in weight of a few pounds

was apparent clinically during the summer months. There was no gross edema at any time during the charted period.

The indication for an injection has been the occurrence of dyspnea, most distressing in the morning before breakfast. The only physical sign that correlated with this symptom was the occurrence of about two fingerbreadths of dullness at the base of the right or left chest. With the salyrgan injection, a loss of three or four pounds in weight would ensue with relief of the dyspnea and disappearance of the basal dullness.

Besides the digitals he received 15 grams of urea in 45 cc of water every morning.

An accurate record of the salyrgan injections prior to September, 1932, is not available but from September 13, 1932, to June 29, 1933, he received 63 injections, usually of 2 cc each. It is believed from a record of the number of ampules used that he has received well in excess of 150 injections in all between April, 1932, and December, 1933.

In a cardiac life that has been decidedly stormy at times, salyrgan apparently is this man's one dependable anchor to windward. The critical period of decompensation that supervened during its omission

in the summer of 1932 suggests that he could not carry on his limited activities successfully without it.

SUMMARY

This is the report of a man, now 73, handicapped by arteriosclerotic heart disease, whose compensation is maintained by the accessory use of intravenous injections of salyrgan. In the past twenty months he has received at least 150 injections with no demonstrable ill-effects.

A NOTE ON THE HISTORY OF LEAD POISONING IN BOSTON*

BY REGINALD FITZ, M.D.†

TO my mind, part of the pleasure of pretending to be an amateur medical historian lies in the fact that one's imagination has so much scope. One can say and even believe many things which may or may not be strictly true and yet which appear incapable of contradiction. As an example of what I have in mind, take the matter of the history of Lead Poisoning. It is generally stated that the ancients knew a good deal about the dangers of lead and were familiar with the clinical manifestations of lead poisoning. Yet it was not until 1767 that Sir George Baker reported to the College of Physicians regarding the Devonshire Colic, and proved that the belly-ache which afflicted the cider drinkers of the South of England was due to contamination of their brew with lead. This report from the time it was read caused great discussion and therefore is properly regarded as an important addition to medical knowledge. Sir George's paper still is most interesting and convincing and I feel sure that the majority of doctors would agree with Dr. Ralph Major and list it as one of the classic descriptions of disease.

I have no desire to belittle Sir George Baker's keenness of observation. But, as a New Englander and a citizen of Boston, I resent it a little that we in Boston have not received so much credit as we deserve for our early efforts to avoid lead poisoning, certainly we were familiar with the dry colic and its cause, and enacted a law to prevent lead poisoning before Sir George

Baker was old enough to be out of swaddling clothes.

My interest in the matter arose in the following way. A friend of the Library of the Harvard Medical School gave the Library just before Christmas a copy of Baker's "An Inquiry Concerning the Cause of the Endemic Colic of Devonshire." I had never seen the paper before and read it with considerable relish. One part of it particularly interested me. Toward the middle of the paper Sir George says "Dr. Franklyn of Philadelphia informs me, that, at Boston, about forty years ago, leaden worms were used for the distillation of rum. In consequence thereof, such violent disorders were complained of by the drinkers of new rum, that the government found it expedient to enact a law, forbidding the use of any worms, except such only as were made of pure block tin. This law having been enacted, the dry colic was much less frequently heard of than before."

Now Benjamin Franklin was born in 1706, and Baker's contribution was read in 1767. So the law that Franklin remembered must have been passed before 1730, he could not have been very old at the time. Why did the law make such an impression on him that he remembered it all these years? Who in Boston at that early date was a sufficiently keen clinician to recognize lead poisoning and to write a law to prevent it?

One can easily believe that there was a good deal of lead colic around Boston at the beginning of the eighteenth century. Three bits of evidence support this belief.

There is another frequently quoted letter of

*Presented as a short play before the Harvard Medical Society January 30 1934.

†Fitz, Reginald—Associate Professor of Medicine Harvard University Medical School. For record and address of author see "This Week's Issue" page 817.

Franklin's on the subject of lead poisoning which, so far as I know, first received publicity in 1788 when John Hunter published it in a book called "Observations on the Diseases of the Army in Jamaica." It was written to a Mr Vaughan and begins as follows

"Philadelphia July 31, 1786"

"Dear Friend,

"I recollect that when I had the great pleasure of seeing you at Southampton, now a twelvemonth since, we had some conversation on the bad effects of lead taken inwardly and that at your request I promised to send you in writing a particular account

TRANSACTIONS 15

XII *An Inquiry concerning the Cause of the Epidemical Colic of Devonshire.* By George Baker, M.D. Fellow of the College of Physicians, and of the Royal Society and Physician to Her Majesty's Household

Printed by A. COLLEGE, Juny 5 1786

A VERY small acquaintance with the writings of physicians is sufficient to convince us, that much labour and ingenuity has been most unprofitably bestowed on the investigation of remote and obscure causes, while those, which are immediate and obvious, and which must necessarily be admitted, as soon as discovered, have been too frequently overlooked and disregarded. Such a spirit of refinement in theory has in several instances, been the

FIGURE 1 First page of Sir George Baker's paper proving that the Devonshire Colic was caused by lead in the cider

of several facts I then mentioned to you of which you thought some good use might be made. I now sit down to fulfil this promise

The first thing I remember of this kind, was a general discourse in Boston when I was a boy, of a complaint from North Carolina against New England rum that it poisoned their people giving them the dry belly-ache with a loss of the use of their limbs. The distilleries being examined on the occasion it was found that several of them used leaden still heads and worms and the physicians were of opinion that the mischief was occasioned by that

use of lead. The legislature of Massachusetts thereupon passed an act, prohibiting under penalties the use of such still heads and worms thereafter

More recently both Oliver Wendell Holmes and Samuel Abbott Green have attempted to reconstruct the early eighteenth century medical practice of New England and each mentions that cases of dry belly-ache seemed often to have been encountered by our colleagues. Green goes so far as to quote an advertisement which appeared in the *New England Courant* in December, 1722

"For the Good of the Public a certain Person hath a secret Medicine which cures the Gravel and Cholick immediately and Dry Belly Ach in a little Time and restores the Use of the limbs again' (tho of never so long continuance) and is excellent for the Gout. Enquire of Mr Samuel Gerrish Bookseller near the Brick Meeting House over against the Town House in Boston N.B. The Poor who are not able to pay for it may have it gratis

Certainly this advertisement suggests that the "Dry Belly Ach" was common enough and that the association between it and paralysis was then generally recognized the colic being more readily amenable to treatment than the palsy

Finally old Dr Holyoke in 1787 in a communication to the Massachusetts Medical Society grew reminiscent. He says that in the early days of his practice the dry belly-ache was very frequent in Salem but lately had become unusual

Admitting that colic was common in Boston before 1730, and even that the association between it and paralysis was known, yet the person who correlated these findings with the presence of lead in New England rum and enacted a law about it is still a mystery. I believe that something like the following episode took place

There graduated from Harvard College in 1687 a man by the name of John Clark. His grandfather and his father had both been doctors, so perhaps being the third in line he came by successful doctoring rather naturally. In any event this third John Clark was an able man of considerable influence in the community. He was a good preacher and a fine doctor with a large practice. There was scarcely an important funeral in Boston which Dr Clark did not attend in some capacity. Also he was a politician. He was Speaker of the House of Representatives for several years and thus was familiar with the machinery of passing laws, he was an important figure in the House and was in the habit of getting through the legislature such bills as interested him. He had a remarkable brother-in-law whom he thoroughly appreciated a man by the name of Cotton Mather. Mather was a truculent, belligerent soul, out of gear with most people, a born reformer, interested in all manner of things, thoroughly alert to everything that was going on and bristling with energy. Although a minister by profession he became involved in the attempt

to prevent by inoculation the ravages of smallpox in Massachusetts and thus came into intimate contact with Zabdiel Boylston one of the most far-seeing, progressive doctors in our history. These three men, undoubtedly, formed a strong triumvirate.

I can imagine them dining together at their favorite Tavern one day in the early winter of 1723. The fare was simple no doubt, but the conversation serious and interesting. Cotton Mather began it by saying what a pity it was that there was so much drinking nowadays, he had been shocked to discover that in Connecticut there had been excessive drinking among clergymen, even, and he thought such practices ought to be stopped. John Clark, keeping the ball of conversation in play, then remarked that he too was impressed with the apparent ill-effects of alcohol among his patients. It seemed to him, especially among the poor people who drank a good deal of new rum, that he was seeing an undue amount of dry belly-ache and that this often was followed by a peculiar muscular weakness, especially characterized by wrist-drop. He had begun to wonder whether these afflictions were not something more than a just dispensation of Heaven against the intemperate and to think that perhaps the rum which these people drank so freely contained a noxious element. This statement seemed to stir up Boylston. For Boylston said that just lately a young chap called Ben Franklin, the brother of that rascal Jim Franklin, the newspaper man, who was so bitter against inoculation, had paid a call on him Jim, quite properly, had just been put in prison as everyone knew, for expressing certain radical views in his paper, the *New England Courant*. Ben* had decided to keep up the journal until his brother got out of prison and had made himself editor-in-chief and printer. He had determined to be a little circumspect regarding the sort of news he put forth because he had no desire to go to jail also. But the other day a rather startling rumor from North Carolina had come to his ears to the effect that the New England rum which was sold there was poisonous and was giving the people who drank it the dry belly-ache with a loss of the use of their limbs. Should he publish this rumor as an interesting item of news or would it be better policy to keep it dark?

Dr Boylston went on to say that Ben Franklin, unlike his brother, appeared to be a decent young chap with a good deal of common sense. He had gone to some distilleries to see how rum was made. He found that rum was commonly distilled through leaden pipes into appropriate

containers. These looked all right, certainly the rum looked all right, too, smelt all right, and tasted fine. But Franklin wondered whether there could be anything in the lead pipes that was harmful.

Dr Boylston said that at first he was disinclined to take very seriously what Ben Franklin had said. But now he was beginning to wonder. It so happened that within the twelve-month there had come to his attention a most interesting book. Medical books that came from the old country were few and far between, but

FIGURE 3 The title page of the 1716 Edition of the Collected Works of Bernardino Ramazzini, the first doctor interested in Industrial Hygiene.

one of his English friends had sent him a copy of a brand new one, the collected works of a Doctor Ramazzini, a professor of medicine in the University of Padua.

Ramazzini had certain ideas in relation to medicine that were altogether revolutionary. One of them was that certain trades were injurious to health, and he had classified the various illnesses to which workers in the different trades were liable. Apropos of what the Reverend Mather, Dr Clark and young Franklin had been saying, Ramazzini's ideas on the type of sickness acquired by workers exposed to lead, like potters and painters, seemed most striking. Then Dr Boylston fetched his copy of this new book and, translating freely from the Latin, read to John Clark and Cotton Mather the following quotations:

*The first copy of the *New England Courant* edited and printed by Benjamin Franklin was published February 11 1723. It begins: "The late Publisher of this Paper finding so many Inconveniences would arise by his carrying the Manuscripts and publick News to be supervised by the Secretary as to render his carrying it on unprofitable has intirely dropt the Undertaking. The present Publisher having receiv'd the following Piece, desires the Readers to accept of it as a Preface to what they may hereafter meet with in this Paper."

"OF THE DISEASES OF POTTERS"

"The potters use hot calcinated lead for glazing, grinding the lead in marble vases with a smooth piece of wood suspended from the ceiling of their workshop and fitted with a square stone at the other end. They then line the vases with molten lead, using brushes for this process before they put them into the furnace to bake. During this time any poison which the lead contains in a liquid state is taken in by the potters to their mouth and nostrils and the whole body. In a short time they begin to feel seriously ill. First they find that their hands are trembling and soon they become paralysed, splenetic, lethargic, consumptive and toothless; hence one rarely sees a potter whose face is not ghastly and leaden."

OF THE DISEASES OF PAINTERS

"Painters are also subject to various diseases such as trembling of the limbs, consumption, blackening

stomach and both the hypochondria, that neither clusters, fomentations, baths nor any sort of remedy gave him ease. The only relief he had in the violence of the fits was to have three or four men leaning with all their weight upon his belly, the compression of which lessened the torment."

John Clark and Cotton Mather were as much struck by these paragraphs as was Dr. Boylston. After due consideration and discussion they agreed that without doubt it seemed highly probable from these observations that lead, even in small quantities, might be very harmful if introduced over a long interval of time into the body. Finally, Cotton Mather, as a notorious reformer, glad to reform anything in sight, turned to John Clark and suggested how salutary it might be particularly as it would make distilling more difficult and therefore less popular, for Massachusetts to be guided by Professor Ramazzini's belief to issue a warning that lead was poisonous, and to have a law enacted which should prevent hereafter the use of lead pipes in the manufacture of rum. Boylston and Clark acquiesced. And so it happened that a law dealing with the regulation of the distillation of rum was proposed by Dr. John Clark and was passed and published on September 3, 1723. The law begins as follows:

"An Act for Preventing Abuses in Distilling of Rum and Other Strong Liquors With Leaden Heads or Pipes

Whereas the strong liquors and spirits that are distilled through leaden pipes are judged on good grounds to be unwholesome and hurtful notwith

FIGURE 3. Title page of Thomas Cadwalader's essay on The West India Dry-Gripes. This essay contains a good clinical description of Lead Colic as it occurred among drinkers whose rum was impregnated with lead.

of the teeth, pallor of the face, melancholy, loss of the sense of smell. The principal cause of their sickness is the material of their colors which they have in their hands continually and under their nostrils such things as red lead, cinnabar, white lead, varnish, nut oil and linseed oil which they use to temper their colors and several other paints made of various minerals. Besides when the painters are about their work they generally wear dirty and stained clothes so they can not avoid taking in offensive exhalations at their mouth and nostrils. Fernelius mentions the curious case of a painter of Angers who was taken first of all with trembling in his hands and fingers. He soon had a convulsion and then his whole arm was attacked by the same disease. This went then into his feet, and finally he was taken with such violent pain in his

FIGURE 4. The Boylston Medical Library Book-Plate. This library is the chief foundation on which the present Harvard Medical School Library rests.

standing which some persons to save charge may be led into the making or using of such heads, worms or pipes for remedy and prevention whereof—

"Be it enacted by the Lieutenant Governor Council and Representatives in General Court assembled, and by the authority of the same

"No leaden heads or worms to be used in distilling, upon penalty

(Sect. 1) That no person whatsoever shall make use of any such leaden heads or worms, for the future, and that whosoever shall presume to distill, or draw off any spirits or strong liquors thro' such leaden heads or worms, upon legal conviction thereof before any of his majestie's courts of record, shall forfeit and pay a fine of one hundred pounds

"And be it further enacted by the authority aforesaid,

No braziers, &c, to make worms or heads of base pewter or lead
Penalty

(Sect. 2) That no brazier, pewterer or other artificer whatsoever, shall presume to make any worm or head, for distilling, of coarse and base pewter, or such as hath any mixture of lead in it, under the penalty of one hundred pounds"

My tale is not as altogether fanciful as it may sound. Lead colic in those days, after all, was typical and fairly easy to recognize. The nearest approach to a contemporaneous account of it as occurring among the rum drinkers of Boston is that given in 1745, by Thomas Cadwalader of Trenton.

In that year he wrote and had published by Benjamin Franklin "An Essay on the West-India Dry-Gripes with the Method of Preventing and Curing that Cruel Distemper" and described several cases which he had encountered. In the West Indies it was the habit to distil rum through leaden pipes so presumably Cadwalader's cases were much like those in Boston. The disease was attended with excessive griping pain in the pit of the stomach and bowels, "a Sensation as if the Bowels were drawn together by Ropes". There was likely to be some nausea and vomiting. Obstinate con-

stipation was the rule. A palsy was likely to ensue when the patients would "lose the Use of their limbs, the ancles and Wrists becoming exceeding weak and the Balls of the Thumbs sinking". Occasional cases were met with which developed violent convulsions. John Clark and Zabdiel Boylston, certainly, were sufficiently practised clinicians to recognize when they encountered so striking a train of events.

There is no doubt but that the law which I have quoted was passed. There is no doubt but that John Clark had a hand in its passage. From the wording of the law one can reasonably conclude that the clinical manifestations and cause of lead colic were recognized by the doctors of Boston in 1723, many years ahead of the rest of the medical world. The passage of so sensible a law pertaining to Industrial Hygiene and Public Health at so early a date in our history is another pioneer medical accomplishment of our fathers, in which Bostonians may well take a justifiable pride.

Whether Cotton Mather, Zabdiel Boylston and Benjamin Franklin had anything to do with the affair is less certain. All I am sure of is what Franklin has written, that the copy of the edition of Ramazzini to which I have referred was published in 1716, and that it wears the book-plate of the Boylston Medical Library.

This library was established in Harvard College in 1802, by Ward Nicholas Boylston, a grand-nephew of Zabdiel. It is said to have been founded as a special tribute to the elder Boylston by the younger. I cannot trace the history of this particular volume. Perhaps this book may have been the nucleus of the Boylston Medical Library, may once have been owned by Zabdiel Boylston, have been studied by him, and used by him as I have suggested. Anyway, as I turn over its pages, I like to pretend that this is so.

VERMONT STATE MEDICAL SOCIETY

SYMPOSIUM

INTRACRANIAL LESIONS*

BY GILBERT HORRAX, M.D.†

Mr President, Ladies and Gentlemen

IN casting about for a subject upon which I might address you for half an hour, it was obvious that I could merely dwell on a few of the high points concerned with recent advances in the field of intracranial surgery. For this reason it would seem most practicable to take up the subject under the following headings:

- 1 Trigeminal neuralgia
- 2 Congenital defects
- 3 Infections
- 4 Traumatic lesions
- 5 Tumors

Just a word about trigeminal neuralgia. It is our practice to be relatively conservative in respect to this condition, because notwithstanding the fact that many patients have a chronic recurring neuralgia for which they must have eventually the so called radical operation of root

*Read before the Vermont State Medical Society at the Annual Meeting held in Barre Vermont, October 5 and 6 1933.
†Horrax Gilbert—The Lahey Clinic Boston Massachusetts.
For record and address of author see This Week's Issue page 817.

resection, nevertheless there are many milder cases which may be controlled easily and quickly, even though temporarily by simple means. In the mild early cases inhalations of trichlylene (trichlorethylene) may be given at times with distinct benefit. Twenty to twenty-five drops of this drug should be inhaled by the patient while lying down, instructions being given to inhale deeply and with the patient lying on the side. This latter precaution is necessary since at times the inhalations may induce a momentary anesthesia in which case the gauze or handkerchief will fall away from the nose and no more will be inhaled. I have never known any deleterious effects from such a momentary anesthesia. Inhalations should be kept up regularly three times a day for several weeks unless the pain becomes severe, in which case the next step in our practice would be to give an alcohol injection. Although injections do not give permanent relief, we believe they should always be given at least once before root resection is performed. There are many reasons for this. In the first place, the patient ordinarily can be given immediate and complete relief from the extreme pain from which he or she is suffering, since the injection can be done in the office. In the second place, the temporary anesthesia produced by the injection gives the patient an idea of the peculiar feeling he will have permanently after root resection. This is important, because some patients find this numbness extremely disagreeable and complain of it afterwards as being almost as bad as their old pain. Thirdly, there are many patients who are far advanced in years and although they might go through the operation perfectly well nevertheless a simple injection which often stops their pain for one or two years may see them through their lives without the added risk of operation.

When injections become difficult or impossible because of the formation of scar tissue produced by the reaction of the alcohol, we must then divide the sensory root of the nerve. We believe the standard operation by the temporal route is the procedure of choice, since the suboccipital operation being entirely intradural almost certainly carries slightly greater risk.

Having thus briefly and necessarily imperfectly spoken of the treatment of trigeminal neuralgia, I may turn for a moment to some other intracranial conditions. Of congenital anomalies, I will speak of one only, namely oxycephaly. This is a rare condition caused by premature closure of the cranial sutures. Due to this fact the growing brain can expand in only one direction which is upward in the region of the anterior fontanelle. This gives the head in such children the peaked appearance known as tower skull. In all of these patients there is definitely increased intracranial pressure as evidenced by marked convolutional atrophy and a

low grade of choked disks with gradually forming optic atrophy. In young children the procedure of choice is to remove large areas of bone from the skull without opening dura. This gives the brain a chance to expand normally while new bone is taking the place of that which has been removed. In older patients a unilateral or bilateral subtemporal decompression should be carried out in the usual way, the dura being opened widely over the temporal region.

Under infections there are two conditions which may have a surgical bearing, namely, non-meningococcal meningitis and brain abscess. Occasional cases of early meningitis have perhaps been cured by laminectomy and drainage of the subarachnoid space, but on the other hand about an equal number have gotten well after repeated lumbar punctures. Concerning brain abscess let me emphasize one or two points. Multiple metastatic abscesses, so far as I know, cannot be helped by any means. Single encapsulated abscesses, especially if they can be approached where they come close to the surface of cortex offer a very good chance of cure. Brain should be removed down to the upper pole of the abscess and the latter aspirated with as fine a needle as possible. The abscess wall should then be opened by crural incision and the four flaps thus created sewed to the subcutaneous tissues. This creates the abscess into a pouch and it will thus drain perfectly. Gutta-percha tissue is laid in the cavity and into this a piece of gauze is packed lightly merely to hold the pouch open. Dressings are then done every other day, and, as the brain around the abscess cavity expands, the abscess wall is gradually pushed outward, thus little by little extruding the drain which may be cut off from time to time. During this time brain and abscess wall will bulge out in the form of a fungus but when the drain has been extruded entirely, the fungus which has by this time granulated over, will recede by itself as epithelium covers it. It is, therefore, not necessary to do anything with such a fungus except to dress it with some smooth material like gutta-percha tissue and keep pressure from it.

Injuries Certain aspects of head injuries were dealt with by your president in his opening address and I shall therefore, confine myself to two of the complications for which one must be on the lookout under some circumstances. Extra-dural or meningeal hemorrhage as you have heard already, occurs shortly after an injury which ordinarily has caused a linear fracture in the temporal region. It is a surgical emergency and must be dealt with promptly. There is another type of slowly developing clot, however, which may not manifest itself for weeks or months after the accident, and it is almost characteristic of this condition

that the injury which causes it is relatively slight. This is the subdural hematoma, formerly called pachymeningitis hemorrhagica interna. After a free interval of a week or two up to several months, the patient usually has headaches which become increasingly severe, sometimes of agonizing severity. There may be also vague mental changes and, rarely, outspoken neurological signs together with choked disks. The differential diagnosis must be made of such a clot and the more frequent conditions of post-traumatic headaches of other origin. In most instances, this must be done by a small trephine opening over the postparietal region on either side of the median line. If a clot is present, the dura will be discolored a greenish blue and upon opening the dura the grey, connective tissue membrane which surrounds the hematoma will present. This membrane should be incised and if the clot has liquefied it may be allowed to evacuate itself so far as possible after which a small soft catheter may be introduced and the soft portion of hematoma further sucked out. If it is solid a bone flap must be turned down and the hematoma with its enclosing membrane evacuated. The mortality from these operations is relatively very low and as a rule, complete convalescence ensues.

Another, though much rarer complication of certain head injuries is the condition of intracranial aerocele. It is particularly likely to happen in extensive injuries involving the frontal and ethmoid sinuses. The patient may do very well for a time and then after sneezing or coughing, headache develops. X-rays will then show the collection of air, which is not only within the cranium but as a rule within the brain substance. In these patients there is a traumatic fistula through the dura into the brain communicating with either the frontal or ethmoid sinus. If nothing is done, the air almost inevitably ruptures into the lateral ventricle, cerebrospinal rhinorrhea is established and a fatal meningitis follows. The treatment is prompt operative intervention, in which the fractured area is reexplored, the fistulous opening sought for and closed either by suture or by placing a piece of muscle or fascia over it, thus sealing it off. The air will then gradually absorb.

Tumors. There is such a short time left to deal with this large subject that I shall confine my remarks to a few of the many groups of tumors about which we have learned a good deal during the past ten years especially.

Gliomas, as you doubtless know, constitute the largest single group, contributing some 40 per cent of all brain tumors. In adults there are two principal types, the glioblastomas and the astrocytomas. The former are the malignant, infiltrating growths and little can be done for

them unless they are fairly small and occupy a silent area of the brain such as one of the occipital or frontal lobes or the right temporal lobe. In such instances, the whole lobe may be excised with the tumor, but even then it may be found that growth has spread beyond the limits of excision, and recurrence, therefore, will take place. The astrocytomas are more slowly growing and less infiltrating. They may be solid or cystic. If solid, they must be dealt with as radically as possible, excising as much cortex around them as can be accomplished without getting into important areas. If they are largely cystic, they offer a better prognosis inasmuch as the cyst can be emptied and the solid portion of growth in the cyst wall excised. Such cases may be completely cured.

In children, there are likewise two main forms of glioma, both occurring in the cerebellum. The medulloblastomas are the malignant type, but as these tumors are highly radiosensitive the patient may often be given a period of one to two years of excellent health. The ultimate prognosis, however, is bad. The other type, as in adults, is the astrocytoma, but in children these are usually cystic growths and may often be successfully dealt with by excision of the nodule of tumor within the cyst.

Another large group of brain tumors are the meningiomas. These are the well encapsulated, solid growths occurring almost without exception in adults. Successful extirpation of these tumors usually results in complete cure, but as they, together with the overlying bone and dura are extremely vascular, the operation may be one of the most difficult that a neurosurgeon is called upon to perform. Meningiomas in the motor area frequently cause focal convulsions of the opposite side of the body, either with or without symptoms of increased intracranial pressure. Furthermore, these growths in any situation, tend to give bony changes which may be recognized by the x-ray. These changes are most often in the form of bony proliferation, sometimes seen as a localized area in the cranial vault directly over the meningioma, while at other times there may be thickening along the base at the site of attachment of tumor to dura. One particular variety causes such thickening of the posterior orbital wall as to give the patients a marked protrusion of the eye on the affected side.

The last group of tumors of which I wish to speak are those arising from the sheath of the acoustic nerve. These are the typical cerebello-pontile angle tumors. Patients harboring this type of growth present a definite train of symptoms and neurological findings which are almost pathognomonic. Their history begins with tinnitus followed by gradually increasing deafness in one ear. After an interval of months or even

years, cerebellar symptoms such as unsteadiness in walking or difficulty in the use of the hands may arise. These are often preceded by a feeling of numbness on the side of the face corresponding to the deaf ear. Finally headaches occur followed by failure of vision and in the end difficulty in talking and swallowing. Neurological examination confirms objectively the symptoms complained of and the ophthalmoscope reveals bilateral choking of the disks if pressure is far enough advanced.

Although acoustic tumors are benign, encapsulated growths, nevertheless they are difficult of access in the cerebello-pontile angle. An intracapsular enucleation is about the best that can be hoped for in most instances, but many times this is sufficient to give a period of many years' relief from symptoms.

MISCELLANY

SPECIAL MEETING

Under the combined auspices of the University of Vermont and Vermont State Medical Society a special clinical meeting will be held in Burlington Vermont, May 4 and 5. A full program will be sent in due time to each member of the State Society.

VERMONT DEPARTMENT OF PUBLIC HEALTH

FEBRUARY, 1934

The incidence of communicable diseases during the month of February is as follows: chicken pox 228, diphtheria 3, measles 238, mumps 32, poliomyelitis 1, scarlet fever 58, typhoid fever 3, undulant fever 2, tuberculosis 10 and whooping cough 155.

A total of 1228 examinations was made by the Laboratory of Hygiene in February, classified in the following manner:

Examinations for diphtheria bacilli	92
" Widal reaction of typhoid fever	30
" undulant fever	14
" gonococci in pus	95
" tubercle bacilli	170
" syphilis	438
of water chemical and bacteriological	23
" water, bacteriological	184
" milk market	88
" milk submitted for microscopical only	0
" milk, submitted for chemical only	9

Examinations of foods	2
" drugs	0
" for courts, autopsies	2
" evidence of rabies (animal heads)	0
" evidence of malaria	1
" miscellaneous	71
" for courts, miscellaneous	7
Autopsies to complete death returns	2

Twenty-four cases of gonorrhea and twenty-one cases of syphilis were reported to the Division of Venereal Diseases. Seven hundred and four Wassermann outfits and 356 gonorrheal slides were distributed during the month.

Eighty-two patients were seen during February by the Poliomyelitis After Care nurses; four doctors were consulted, five social service calls made, five plaster casts removed, three patients were admitted to the Children's Hospital and four discharged from the same hospital. One patient was admitted to the Audubon Hospital and two discharged from this hospital. Three new pieces of apparatus were fitted and 12 orthopedic corrections made to shoes. The vocational worker of this division reports sales made by the patients amounting to \$22.42.

BURLINGTON AND CHITTENDEN COUNTY CLINICAL SOCIETY

The following is the report of the Secretary of the meetings held by the Burlington and Chittenden County Clinical Society since November, 1933.

At the December 21st meeting Dr. Truax gave a very interesting paper the subject of which was 'Gentian Violet Treatment of Cutaneous Burns.' He outlined the advantages of this treatment in the more severe types and brought to the attention of the members the fact that these burns should not be covered with ointment before being sent to the hospital as it makes treatment more difficult for the attending surgeon.

Dr. F. L. Hall of Grand Isle was elected to membership.

At the meeting on February 15, Torr Wagner Harmer, M.D., Chief Surgeon, Out Patient Department, Massachusetts General Hospital, presented a paper on 'Hand Surgery,' which was divided into three sections, as follows: 1. Infections, 2. Trauma, 3. Reconstruction. This paper was ably illustrated by many lantern slides. Dr. Harmer brought to the attention of the members the fact that a thorough knowledge of the anatomy of the hand is vitally important to anyone doing this type of surgery.

Dr. Harold L. Medevitsky was elected to membership.

NEW HAMPSHIRE MEDICAL SOCIETY

ONE HUNDRED AND FORTY-THIRD ANNUAL MEETING

Preliminary Announcement

Doctor Dean Lewis, President of the American Medical Association and Professor of Surgery at the Johns Hopkins Medical School, Doctor Walter C Alvarez of the Mayo Clinic, Doctor Frank E Adair, of New York City, and Doctor S A Petroff, of Saranac, will be among the out of state guests at the annual meeting of the Society, which will be held at the Hotel Carpenter, Manchester, on May 15 and 16, 1934

All meetings will be held on Eastern Standard Time

With the President, Doctor Robert J Graves of Concord, in the Chair, the scientific sessions will open promptly at 10 o'clock (A.M.), on Tuesday, May 15 and continue with morning and afternoon sessions Tuesday and Wednesday. The afternoon sessions will begin at 2 00 o'clock. On Tuesday evening there will be an entertainment in the Assembly Room for the members of the Society and the members of the Women's Auxiliary. On Wednesday evening the usual banquet will be held with Dr James J Powers, of Manchester, acting as Anniversary Chairman

On Tuesday morning there will be reports of committees. Full details will appear in the *Journal* next month

On Tuesday afternoon, May 15, at 2 00 o'clock there will be a symposium on Pulmonary Tuberculosis. Doctor Petroff and Doctor Deming, of Glencliff, will consider the medical aspects, Doctor Richard Overholt, of Boston, will discuss the surgical aspects and Doctor A. S. Merrill, of Manchester, will describe the x ray findings

On Wednesday morning, May 16, beginning at 10 00 o'clock, Doctor William P. Murphy, of Boston, will speak on Anemia, and Doctor Dean Lewis will follow with an address to the Society. On Wednesday afternoon, beginning at 2 00 o'clock, Doctor Alvarez and Doctor Adair will be on the program. The usual number of papers with discussions will complete the programs on both days. Several of the out of state guests will be present and speak at the banquet

The first meeting of the House of Delegates will be held Monday evening, May 14, at 7 30 o'clock at the Hotel Carpenter and all subsequent meetings will be at the same place. Henry C Sanders, Jr., of Claremont, will be the Acting Speaker

The usual exhibition of surgical instruments, x ray appliances, drug specialties and books will be held in the hotel lobby

All arrangements for the meetings and exhibits are under the management of the Manchester Medical Society. Howard A. Streeter, Chairman

The Women's Auxiliary will hold its Annual Meeting during our sessions. Its members and other visiting women will be entertained by the Committee on Entertainment of Visiting Women

A detailed program will be printed in the *Journal*

next month and will be mailed to all members of the Society

ROBERT J GRAVES, *President*
CARLETON R. METCALF,
Secretary Treasurer, Pro Tem
HENRY C SANDERS, JR.,
Acting Speaker of the House
of Delegates

GOLD MEDALISTS

Gold medals will be presented to Leonard Jarvis, of Claremont, and to George E. Leete, of Concord, who have attained fifty years' membership in the Society

NEW MEMBERS

Bassow, G. W., East Jaffrey
Bennert, H. W., Goffstown
Benway, C. A., Bristol
Burroughs, T. P., Concord
Butterfield, Warren H., Concord
Crisp, N. W., Nashua
Daniels, B. P., Keene
Eades, G. R., Keene
Eastman, C. D., Monroe
Goodlett, W. C., Lisbon
Goodman, P., Nashua
Hamel, P. R., Manchester
Harrington, W. J., Manchester
Hernandez, R. A., Laconia
Jacques, Laura, Tilton
Jones, R. N., Whitefield
Kasheta, F. J., Warren
LaFrance, Phillip, Laconia
LeBlanc, J., Suncook
McDonald, W. J., North Conway
Murphy, R. L., Manchester
Nolin, Francis H., Claremont
Norris, J. L., New London
Phillips, Arthur, Potter Place
Precourt, W. E., Somersworth
Prevost, G. E., Keene
Prince, W. M., Durham
Rahmanop, W. B., Dover
Robbins, M. J., Nashua
Robinson, Norris, Keene
Sanders, James, Rye
Shields, J. D., Concord
Sikorsky, Lucy N., Claremont
Spring, J. D., Nashua
Stewart, Melba, Laconia
Thibodeau, W. D., Nashua

IN WEEKLY CLINICAL-PATHOLOGIC EXERCISES

EDITED BY RICHARD C CABOT, M.D.
F M PAINTER, A.B., ASSISTANT EDITOR

CASE 20151

PRESENTATION OF CASE

A thirty year old divorced American laundry worker entered complaining of profuse vaginal bleeding

Her menstrual periods had always been regular until nine years before entry. At that time without any known cause her periods became irregular, occurring every two to four months and lasting for several weeks or months. The amount of bleeding greatly exceeded that of her usual periods. A surgeon removed several uterine polyps at that time. For the next year she had no bleeding at all and felt much better, then the same symptoms recurred. She also complained at that time of a dull dragging feeling in the lower abdomen but no actual pain. Two years before entry she received four x-ray treatments without relief. Her condition remained about the same until six or eight weeks before entry at which time the bleeding became worse, requiring four heavy pads a day. She felt very tired and was forced to give up work. Two weeks before entry she fainted. A doctor packed her uterus. Since that time she had had two other packings. The weakness increased and was often associated with periods of dizziness. During the last two weeks before entry she had occasional nausea and vomiting, and dull lumbar backache relieved by standing up.

She had gained about forty pounds during the past five years and stated that she had felt rather apathetic and had lost interest in her surroundings, although her memory and intellect remained as before. There was no enlargement of her tongue or difficulty in speaking.

Her father, mother, three brothers and three sisters were all living and well. There was no family history of diabetes, cancer, insanity or typhoid fever.

She was married fourteen years before entry and was divorced nine years later. Her husband had tuberculosis. There were no pregnancies.

She had an appendectomy sixteen years before entry. Her catamenial history was normal. Periods began at the age of twelve and were regular until the onset of her present illness.

Physical examination showed a well devel-

oped, very obese, pasty woman, weighing approximately 190 pounds. Her hands and feet were very small. She wore a size four shoe. Most of her obesity was abdominal and thoracic. The breasts were large and pendulous. The thyroid was palpable, moderately soft and symmetrical. There was extreme tenderness over the midlumbar spine. The abdomen was large, flabby, and showed striae albicantes. There was slight tenderness in the left lower quadrant. The fundus of the uterus was palpable. There was profuse vaginal bleeding.

The temperature was 98.4°, the pulse 85. The respirations were 20.

Examination of the urine (not a catheter specimen) was negative except for occasional white blood cells. The blood showed a red cell count of 3,890,000, hemoglobin 60 per cent, and a white cell count of 14,350, with 72 per cent polymorphonuclears. Examination of the stools was negative. The clotting time was three minutes. The bleeding time was not prolonged. The basal metabolic rate was -15. The blood calcium was 10.19 milligrams per 100 cubic centimeters. The phosphorus 3.72.

X-ray examination of her skull showed a normal sella turcica. There was some increase in porosity of the bones of the skull otherwise they showed no variation from the normal.

She was given iron and ammonium citrate grains ~~xxx~~ three times a day. Five days after admission she was given ten subcutaneous doses of autophycin, one hundred units daily. During this treatment there was practically no appreciable rise in temperature although at times she felt dizzy and weak, and there was no appreciable diminution in her vaginal bleeding. She felt very weak and complained of severe left lower abdominal cramps. On the nineteenth day dilatation and curettage was done.

DIFFERENTIAL DIAGNOSIS

DR GEORGE A. LELAND, JR. It appears that this patient is a woman of thirty who for one half of her normal menstrual life has had abnormal uterine bleeding. In spite of the fact that according to the record there were no pregnancies, I do not think one can exclude the possibility that we may be dealing here with one of the abnormal bleedings incident to pregnancy. The retained placenta in an interrupted pregnancy may produce very prolonged bleeding. On the other hand one would not expect such a situation to last for nine years.

It was noted that in the early part of her history a doctor removed several uterine polyps. That, if true, is very important. It is rather unusual to make the diagnosis of multiple uterine polyps. Multiple cervical polyps are not rare and can be easily diagnosed without opening the uterus. The diagnosis of multiple uterine polyps usually requires a hysterotomy either on the operating table or on the pathologist's

table If there were multiple tumors removed by this physician one wonders if they were typical polyps or of the hydatidiform mole type. However, we will let that go by and assume that the history is correct, that there were no pregnancies and that the duration of the bleeding excluded the suspicion that it might be caused by pregnancy.

In a woman of thirty, cancer cannot be excluded. About four per cent of all cancers of the cervix occur in women of thirty years or younger. But here again the duration of the bleeding symptoms is too long to indicate that we have a cancer of the cervix. No mention is made of the cervix in the report of the physical examination. Whether it was palpated or not we do not know. Adenocarcinoma of the uterus is extremely rare but not unknown in women of this age. There again we would not suppose that adenocarcinoma would account for all the symptoms. Suppose, however, that she had had uterine polyps at one time and that they have recurred, it would not be impossible to have a later development of adenocarcinoma superimposed upon recurring uterine polyps.

A third condition to be considered is the question of thrombopenic purpura. In most cases of thrombopenic purpura however in women of this age the periods are not so irregular as they were here. In a typical case the bleeding is prolonged with each period, but the periods are regular. Then too we would expect a story of bleeding from other organs. In this case we have the blood examination showing that the bleeding time was normal. These negative findings would seem to rule out thrombopenic purpura as a possibility.

Coming to the pelvis itself, we have a history of uterine polyps. We have upon physical examination the finding that the fundus of the uterus was palpable. A uterine fundus palpable through an abdomen which was very obese would indicate definitely that the fundus must be considerably enlarged. One must not forget the possibility however that the palpable mass was not the fundus at all, but an ovarian tumor. If the story that there were polyps is true, with this finding of enlarged fundus one has the right to assume that this patient at the time of her entrance had multiple fibromyomata of the uterus, probably with recurrent polyps with, possibly, superimposed adenocarcinoma.

When we take the story as a whole and examine the physical condition critically we find that the most striking thing of all is of course the great weight of the patient. The distribution of the fat combined with the small hands and feet—(the shoe was size four, distinctly the Cinderella type)—this disproportion of the hands and feet to the fat chest, abdomen and pendulous breasts of course brings up at once the question of pituitary disturbance. We find that the basal metabolic rate has been in-

terfered with, and going farther down the abdomen we find that there is distinct evidence of pelvic pathology.

To piece these findings together, I merely recall to your mind that investigative work in recent years has indicated a very definite association between uterine polyps, fibromyomata, and cystic degeneration of the ovaries. The multiple follicular cysts which produce estrin seem to have, in a carefully worked out series, a very close relationship possibly with the formation of fibroids. It has been pointed out that pituitary disturbance will appreciably affect and maintain the permanence of these cysts. So we would hazard a diagnosis in this case of fibromyomata of the uterus with uterine polyps associated with bilateral cystic ovaries with a background of pituitary disease, bearing in mind the remote possibility that adenocarcinoma of the uterus may likewise be superimposed.

DR JOE VINCENT MEIGS I think that Dr Leland has covered the subject very well.

There are two or three things that strike me. One is the lowered metabolism. Some patients with myxedema have abnormal bleeding. Another is that this bleeding might be explained on two bases. One is that she has follicular cysts of the ovary containing estrin, which could be responsible for hyperplasia of the endometrium, which in turn might be responsible for the bleeding, as Dr Leland has just suggested. Another is that she might possibly have a corpus luteum cyst of the ovary or a persistent corpus luteum which would account for her forty day interval between periods and the large amount of flowing at the time she did bleed. There might be an endometrium decidual in type without pregnancy, due to the persistent lutein action.

I do not know whether this is the case here or not, but I remember a patient whom I saw some time ago, a woman who had abnormal bleeding of this type and who had had a trial with the luteinizing hormone and did not respond. She had carcinoma of the endometrium at twenty-nine or thirty years of age. I think that is a very distinct possibility in this case. Also we must bear in mind that the so called granulosa cell type of carcinoma of the ovary secretes estrin, and like simple follicular cyst causes hyperplasia of the endometrium and abnormal bleeding. The description of the patient herself suggests some pituitary dysfunction.

DIAGNOSIS

Adenocarcinoma of the uterus

PATHOLOGIC DISCUSSION

DR TRACY B MALLORY The patient was curetted and the curettage showed material that in gross was obviously carcinoma. Following that she had a hysterectomy. The uterus shows a well-marked adenocarcinoma of the fundus.

The ovaries were not enlarged and contained no cysts of any significant size and no corpora lutea

The long period of purely functional bleeding in this case with the marked suggestion of pituitary disturbance would tremendously tempt one to consider it solely a functional case

The possibility of carcinoma even at such a very early age is well worth emphasizing. It certainly was fortunate that at least at the second curettage a diagnosis of carcinoma was made. It certainly suggests that the carcinoma developed on the basis of long-standing hyperplasia

DR. AUBREY O HAMPTON. I should like to ask Dr. Meigs what bearing he thinks the x-ray treatment would have on the diagnosis. She had a sterilizing dose of x-ray

DR. MEIGS. If the patient did not respond to this treatment carcinoma should be considered in spite of a negative curettage

I think the important lesson to learn and one that we all ought to learn now that we are using hormone treatment, is that it might be very easy to treat a patient with cancer. If you have made up your mind that the bleeding in a case should respond and the hormone does not make it respond there is a great necessity to find out whether there is any malignant lesion present or not

CASE 20152

PRESENTATION OF CASE

A thirty-five year old Lithuanian housewife entered the hospital complaining of excessive uterine bleeding

Her menstrual periods began at the age of thirteen or fourteen and were regular, occurring every three weeks and requiring two or three pads a day. She had no pain and no leukorrhea. Nine months before admission she had flowing for three weeks and again the following month had excessive flowing. The next month she had no menstrual period but the following month, six months before admission she again had excessive flowing. She missed the next two months. Three months before admission she had excessive flowing. The following month the period lasted two weeks. Two weeks before admission flowing began and had continued ever since. She passed a few clots. At no time was there any pain or discomfort in the pelvis or back. During the week before entry she had used from four to seven pads daily and felt somewhat weak. Her bowels were constipated. Her appetite was good. There were no urinary symptoms

She had always been well. There was no history of scarlet fever, diphtheria or rheumatic fever. About three weeks before admission following an automobile accident she had excessive flowing. At that time she had dilatation and

curettage at a hospital. Following this her periods were normal until the onset of her present illness

Her husband and one child were living and well. There had been no miscarriages

Physical examination showed a well-developed and well-nourished woman. There was an occasional extrasystole and a soft systolic murmur at the apex. The blood pressure was 110/70. The lungs were clear. Examination of the abdomen was negative. Vaginal examination showed a large amount of old blood in the vagina. The cervix was lacerated but was not well visualized. It had an eroded lacerated, granular feeling by digital examination. The fundus of the uterus seemed slightly larger than normal. The vaults were clear

The temperature was 98°, the pulse 95, the respiratory rate 20

Examination of the urine showed a specific gravity of 1.034. The sediment contained an occasional white blood cell and large numbers of red blood cells. Examination of the blood showed a red cell count of 4,600,000, hemoglobin 70 per cent. The white cell count was 7,500 with 62 per cent polymorphonuclears

On the fourth day operation was done a trachelorrhaphy supravaginal hysterectomy and right salpingo-oophorectomy. She ran an uneventful convalescence except for a slight fever and slight urinary incontinence. She was discharged on the twenty-first day

CLINICAL DISCUSSION

DR. HENRY H. FAXON. In many respects this case is similar to the one that Dr. Leland discussed and I think that my mind worked in part along similar lines

She was thirty-five years old which puts her in the possible cancer age and also at the approach of the menopause possibly. Her menstrual history had been normal, menstruation starting at the usual time and the flow being regular, although she had run on a three-week cycle, in other words at a shorter interval than the normal twenty-eight days, which would suggest possibly the lack of luteinizing hormone even from the start. She had no pain and no leukorrhea which suggests no pressure in the pelvis, no pelvic inflammation, and no discharge that might come from the cervix. The story of her periods per se was essentially that of menorrhagia and skipped periods. The automobile accident aggravated the condition, but I think was incidental rather than causative in any way

There is mention here that she passed clots. I think no especial significance need be laid to this, although with fibroids the passing of clots is of more frequent occurrence than when they are not present

Her bowels were constipated, but from that one statement alone no special conclusion can

be drawn We do not know whether she was becoming any more constipated or whether constipation was the rule in her case If it had increased it might suggest pressure in the pelvis, but the physical examination failed to disclose any such pressure There are no urinary symptoms

The past history shows no disease that might have sequelae

She had a dilatation and curettage about a month before she entered The physical examination we are given leaves something to be desired in the situation We should like to know what the condition of the cervix was, the size of the uterus, and so forth It seems to me that if she had been recently curetted and examined under ether we might well exclude the possibility of carcinoma of the cervix She had no discharge between periods and no vaginal bleeding I am inclined to think the dilatation that was done a month before helps us to exclude certain pelvic pathology It is of interest that the dilatation did not correct her condition After two weeks she again had an abnormal amount of flowing

She had been pregnant From the story here we do not know how long she had been married or what the age of the child was, but the story is that of only one pregnancy The question comes up as to the possible causes for sterility, and we wonder whether there was a pelvic inflammation of which we have no evidence, or whether a certain amount of ovarian dysfunction might be the cause of her having only a single pregnancy

The fact that she had no miscarriage helps to rule out lues

The blood pressure, the extrasystoles and the soft systolic murmur can be explained on the basis of her blood loss

On pelvic examination the cervix was lacerated but not well visualized As I have said, I should think that any gross pathology would have been discovered at the time of the previous examination and curettage

We are told that the uterus was slightly larger than normal The explanation is either that the uterus was actually normal and the fundus contained a large amount of blood clot, that possibly not the fundus of the uterus but the ovary was being palpated, or else that she had some growth within the fundus of the uterus itself

The urinary findings are a little confusing A large number of red cells was reported, but we are not told whether that was confirmed by a second catheter specimen It seems to me that if real significance (other than vaginal contamination) had been attached to the urinary finding of blood, further investigation would have had to be done to make a definite diagnosis

The blood showed the red cell count to be 4,600,000, which signifies that she had no marked anemia in spite of the continued bleeding

The white cell count was 7,500, showing no evidence of infection or twisted pedicle that might have shut off the blood supply of a pedunculated fibroid or ovarian cyst

It seems to me that the bleeding in this case may have been due to some general blood disease of which we have no evidence, to functional causes, organic causes, or a combination of the latter two

So far as pregnancy and miscarriage go, the story is too long, and furthermore the dilatation and curettage rules out the possibility of incomplete miscarriage

Indirectly the pituitary, or thyroid, or some endocrine gland may have played a part, but there is no evidence of a lowered metabolic rate or of any disturbance of the pituitary

As for an ovarian tumor, it would seem to me that if a cyst of any appreciable size had been present when they examined her under ether they would have been able to detect it

Pelvic inflammation has been fairly well ruled out on the story and the absence of confirmatory physical findings

Malignancy of the cervix I think has to be excluded by the previous dilatation and curettage As to malignancy of the fundus, as Dr Leland pointed out in his case, she is a little young to expect that, and furthermore one would expect that, at the previous dilatation and curettage, diagnostic curettings would have been obtained A polyp of the cervix could be mentioned, but that again is excluded for the same reasons

The points that have been brought out as to the relation between the ovarian function and the occurrence of fibroids are interesting and have been amplified and explained here already

I arrive at the conclusion that the most likely cause of her bleeding was a fibroid of the uterus which was probably submucous and hard to detect both by examination and curettage If it was associated with multiple cysts of the ovary there would be a rational explanation for the operation of supravaginal hysterectomy and right oophorectomy that was done The removal of a single ovary suggests to me that possibly the right ovary was filled with small cysts, whereas the other was of the small sclerotic type My diagnosis here would be fibroid of the uterus with multiple cysts of the right ovary

DR GEORGE A. LELAND, JR. Dr Faxon's reasons are very logical One should have personal knowledge of the surgeon who did the preliminary diagnostic curettage a month before admission in order to be certain in excluding the various serious possibilities Upon curettage it is very easy to fail to find adenocarcinoma of the fundus, and it is not too dif-

ficult to fail to find a very early carcinoma of the cervix. We assume in this instance that the operator did know the man who did the curettage and was confident that the negative findings were in those two respects correct. I am wondering however that the surgeon was bold enough to leave in the cervix when he was going to remove the fundus, assuming that he found fibroids with estrin producing follicular cysts of the ovaries. If he is going to leave in one ovary, he is leaving in with it the cervix and perhaps some endometrial tissue as well. This is a cervix which is already known to be lacerated. There has been one childbirth. It appears to me that in such a procedure there is a slight potential risk of later trouble arising in that cervix.

DR. JOE VINCENT MEIGS: I have very little to say, except that I think the history of skipped periods and then much flowing is quite characteristic of the Shaw group I type of bleeding in

which there are follicular cysts of the ovary, absent corpora lutea, and marked hyperplasia of the endometrium. I also think this type of bleeding could be explained by pelvic inflammatory disease, where follicular cysts of the ovary are not uncommon.

DIAGNOSIS

Menorrhagia

PATHOLOGIC DISCUSSION

DR. MALLORY: The surgical specimen which was removed showed a diffusely enlarged uterus with a markedly hyperplastic endometrium. There was no fibroid. The one ovary which was removed contained, as predicted, multiple follicular cysts and no corpora lutea. Unfortunately we do not know positively what may have been present in the opposite ovary. The findings, so far as they go, fit perfectly into the Shaw group I type of functional bleeding.

ARCHIVES OF PEDIATRICS SEMI- CENTENNIAL NUMBER

THE *Archives of Pediatrics* having been the first journal on the diseases of infants and children published in the English language, its present editors have commemorated its semi-centenary—the original number appeared on January 15, 1884—by devoting the issue of February, 1934 to the reproduction of certain articles appearing in it during the course of its first year.

The cover of the first issue is reproduced, an issue appearing under the editorship of William Perry Watson, A.M., M.D., Physician for Diseases of Children to the Central Dispensary and Assistant to Christ Hospital, Jersey City, N.J. The collaborators at that time were J. Lewis Smith of New York, J. M. Keating of

Philadelphia, F. Forchheimer of Cincinnati, Marcus P. Hatfield of Chicago, Henry D. Ingraham of Buffalo, Joseph P. Oliver of Boston, Edward Borch of St. Louis, William T. Plant of Syracuse and Jerome Walker of Brooklyn. Foreign countries were represented by Goodhart of London, Finlayson of Glasgow, Ashby of Manchester and Blackader of Montreal.

Following are a number of original communications: Convulsions in Children by William T. Plant, Congenital Lipoma by Abraham Jacoby, The Hygienic Management of the Summer Diarrhea of Infants by J. Lewis Smith, Clinical lectures are on Infant Feeding by John M. Keating, Rachitis by F. Forchheimer, and Intestinal Indigestion by Louis Starr. Clinical memoranda are contributed by L. Emmett Holt, William P. Northrup and Henry Dwight Chapin.

A characteristic feature of these communications of fifty years ago is their clinical nature and the accuracy of their detailed descriptions of signs and symptoms. Thus Plant, in his paper on convulsions in children: "The whole body is in violent, uncontrolled action. The facial muscles are twitching, giving to the features the most frightful expressions. The mouth is distorted, and often the lips and chin are covered with a bloody foam. The eye-balls are turned up under the lids, or to one side, or are rapidly jerked this way and that. The lingual muscles take part in the general mêlée and frequently the tongue is severely lacerated by the teeth. The head is drawn backward or to one side by a succession of spiteful jerks. Generally the face is livid from congestion, exceptionally it is pale. The arms and legs are in ceaseless convulsive movement. The forearms are rapidly bent and extended on the arms, there are alternate movements of incomplete pronation and supination and the limbs are twisted and drawn into various awkward and grotesque shapes. Usually, the legs are less roughly dealt with than the arms."

A touch of humor is added and advice with a reminiscent note is given to the young physician on first encountering a case of convulsions: "Here are good ladies longing to be of use, give them something to do. Ask one of them to provide a plentiful supply of hot water, and another to look up a bath or wash tub. If the child is in a small room, assign to another the task of carrying it to a larger one and loosening the clothing at the neck and waist."

This number, collected from the archives of a half century ago, is well worth perusal. Some of its contents might not stand the scrutiny of modern scientific exactitude but their descriptions of disease are classical and the sound common sense introduced might afford an example to more modern writers.

A NEW APPARATUS FOR INVESTIGATION OF THE NERVOUS SYSTEM

An electrical device has recently been designed by Dr Richard U Light of the Yale University School of Medicine and Professor E L Chaffee of the Department of Physics of Harvard University for experimental exploration of the functions of the nervous system. By an ingenious method of implanting small secondary coils in an animal at excitable centres and then by bringing the subject into a magnetic field created by a primary circuit, Jacksonian attacks from stimulation of the motor area in the monkey a condition of somnolence after excitation of the hypothalamic region contraction of the tongue from implantation of the electrodes on the hypoglossal nerve and a copious flow of highly acid gastric juice and violent peristalsis, from stimulation of the vagus on the lower esophagus of a dog have been repeatedly demonstrated. Some of the implanted coils, covered with collodion have remained in place for as long as seven months without evidence of irritation of tissue or of cyst formation. By this method the restrictions of time, anesthesia and restraint of the animal are removed and a wide range of exploration of function is possible. The exciting stimulus may be activated over months without disturbing in any way the habits or activity of the animal. Thus a new and important principle of investigation has been invented which should be particularly useful in the study of such autonomic functions as sleep, sugar and water metabolism, menstruation, blood pressure digestive activity and temperature control. The possible results of research by this apparatus are of the greatest interest in the wide field of medical science. A preliminary report of this important work has been published in *Science*, March 30 1934.

THIS WEEK'S ISSUE

CONTAINS articles by the following named authors

TRUESDALE, PHILEMON E. M.D. Harvard University Medical School 1898 F.A.C.S. Surgeon, Truesdale Clinic Fall River Massachusetts. His subject is "Hernia of the Diaphragm. Esophageal Type In Adults." Page 781. Address 151 Rock Street Fall River, Massachusetts.

The Massachusetts Medical Society

THE TREASURER'S REPORT

COVERING REFUND DISTRIBUTION

THE Treasurer of the Massachusetts Medical Society makes the following report regarding the refund to District Societies for 1934

The Council voted to distribute the sum of \$5000 to District Societies The total number of payments of annual dues received by the Treasurer, for March 1st and to be counted for the refund was 3229 Therefore the refund to the District Societies for each paid Fellow is \$15484

The following table gives the number of payments in, and the refund to, each District

District	Number Reported Paid	Check
Barnstable _____	35	\$54 21
Berkshire _____	80	123 88
Bristol North _____	51	78 98
Bristol South _____	145	224 53
Essex North _____	136	210 59
Essex South _____	163	252 40
Franklin _____	31	48 02
Hampden _____	182	281 82
Hampshire _____	40	61 95
Middlesex East _____	82	126 98
Middlesex North _____	89	137 82
Middlesex South _____	571	884 15
Norfolk _____	563	871 76
Norfolk South _____	82	126 98

Plymouth _____	96	148 66
Suffolk _____	503	778 86
Worcester _____	323	500.14
Worcester North _____	57	88.27
	3229	\$5000 00

In 1933, for comparison, the total number of payments for the refund was 3177

CHARLES S BUTLER, M D, *Treasurer*
April 2, 1934

MASSACHUSETTS LEGISLATIVE NOTES

REPORT ON CHIROPRACTIC AND OTHER HEARINGS

On Tuesday, April 3, 1934, there were three hearings before the Legislative Committee on Public Health The hearings had been set on rather short public notice so that they did not appear in the Bulletin of Committee Work for March 26, 1934, and were not noted in the issue of the *Journal* for March 29, 1934

The first bill considered was Senate 162 which accompanied the petition of Joseph Conway for certain amendments to the law relative to registration and practice of chiropractors Mr Conway acknowledged that the Bill as drawn was unsuitable and that an impasse had been reached by the persons favoring and opposing the registration of chiropractors He was confident that a reasonable solution could be reached and asked that a subcommittee of three members of the Legislative Committee on Public Health meet with three physicians, representing the State Department of Public Health, the State Board of Registration in Medicine and the Massachusetts Medical Society and with three chiropractors or representatives of chiropractic to seek a solution in conference and to report their findings to the Legislative Committee

There spoke against the bill, Dr Thomas J O'Brien for the Massachusetts Medical Society, Dr Gaylord W Anderson, Deputy Commissioner of the State Department of Public Health, Dr Stephen Rushmore for the State Board of Registration in Medicine, Mr Frank Kiernan, Executive Secretary, Massachusetts Tuberculosis League, and Miss Dieter for the Massachusetts State Nurses Association. Mr Kiernan referred to several thousand persons who had come to his attention during ten years of work in the State of New York, at a time when they were hopelessly ill from tuberculosis and who in the early and curable stages had been under the care of chiropractors A number of other persons expressed their opposition by a rising vote

The second bill was House Bill 118, introduced by the Board of Registration in Medicine, the most important provision of which would give to the Board discretionary power of approval of medical schools from which graduates are accepted for examination.

The Board was represented by the Secretary Dr Stephen Rushmore, whose remarks appear elsewhere in the *Journal*.*

Dr Anderson, Deputy Commissioner of the State Department of Public Health also spoke for the Bill, on the grounds that increased protection of the health of the people of Massachusetts demanded raising the statutory qualifications for practice. He called attention also to the generally acknowledged inadequacy of the examination test to determine actual fitness for practice.

On account of the length of the hearing it was interrupted by recess and a number of persons registered their approval of the Bill leaving their names with the Clerk of the Committee.

Opposition to the Bill was led by Mr C Ruggles Smith, Registrar of Middlesex College of Medicine and Surgery, who emphasized the importance of having medical schools independent of the control of the "Medical Trust" described in the terms usually employed on such occasions, which, it was alleged, controls all the State Boards of Registration in Medicine in the United States including the Massachusetts Board. Professor Joseph Cheskis of Middlesex College of Medicine and Surgery, perforce described the difficulties of the poor boy in getting an education. The Secretary of the Board had pointed out that one of the not approved schools which advertised as specializing in "poor boys" acknowledged that it could do "little financially" and admitted that "perhaps it was better that it could not help in this way."

Mr William Blatt, Professor of Medical Jurisprudence at the College of Physicians and Surgeons, Boston and Mr George W Boland lecturer on the same subject in the same institution also spoke against the Bill.

The third bill was House 755, introduced by Mr Dever of Cambridge, on petition of C Ruggles Smith for amendment to the law relative to registration of physicians and surgeons. Mr Smith and Mr Boland spoke for it. The first provision of the bill is to make unacceptable as a qualification for admission to examination, attendance at schools not empowered to confer degrees even though legally chartered. The dispute on this point, for no principle is involved seems to concern two factions among osteopathic interests only, for if schools once chartered are permitted to degrade medical education as much as they please the mere lack of power by one medical school to confer degrees would not appreciably affect the health of the public.

The second provision asks for repeal of the section of the Massachusetts statute which empowers the Board of Registration in Medicine to accept the examination of the National Board of Medical Examiners in place of its own examination. It is interesting to note that some persons who opposed giving the Board of Registration in Medicine discretionary power of approval of medical schools, because they know so little about medical education" being by statute not connected with a medical school

should be opposed to the Examiners of the National Board "because they are teachers in medical schools." So completely was the situation misrepresented that the view was expressed that it is not fitting that Massachusetts should accept the dictation of a body from outside the State. As the examinations of the National Board are accepted in over forty states and are generally regarded as more searching and difficult than any State board examination, the hearing showed a somewhat remarkable recrudescence of narrow partisanship and parochialism.

MISCELLANY

MATERNITY DEATHS

In a large American city an eminent board of medical men supervised a study of every maternal death during a period of three years. Competent physicians investigated every death as soon as possible after it occurred. Significant findings were made from the facts found and published under the authority of the local Academy of Medicine.

Of these deaths 658 were preventable. If the care of the women had been proper in all respects

The report states: Any group of deaths in which two-thirds of the total could have been prevented becomes immediately a most pressing problem. The Committee always asked this question: If this patient had had the advantage of the best possible attention and care, would this death have occurred? Where the answer to the question was in the negative they classified that death as preventable.

"There is a responsibility to see that every woman has such care.

It lies with the medical profession as a whole.

It lies with the individual members of that profession.

"It lies with society as it is represented in the numerous organizations for the improvement of the health conditions of that part of the social body which is forced into a greater or less dependence on the public health facilities.

It lies with the woman herself.

Do you think conditions in your own community are much better than this? They are not, unless the death rate reflects it. First, find out what the local mortality rate is—then compare it with the rate of 2.2 per thousand live births, which is the rate actually achieved among more than 5000 mothers cared for during eight years by the Maternity Center Association. The records of these cases were studied and the foregoing figures certified by Dr Louis I. Dublin, Statistician, Metropolitan Life Insurance Company.

MAY DAY—CHILD HEALTH DAY

On May 1 will be celebrated the tenth anniversary of National Child Health Day. In the years since its initiation by the American Child Health Association in 1924 the observance of the day has undergone significant changes. Each year it has

struck a deeper note. Each year new groups have realized that they had a contribution to make. Steadily from May Day to May Day, communities have come to understand that teamwork for child health is for the best interests of children.

Of all the values of May Day—Child Health Day, perhaps the greatest is the opportunity it presents to enlist the active interest of groups which might otherwise not give the subject of child health any particular thought, and to draw them into the general program.

The spirit of cooperation, be it local or state-wide, has been fostered by the activities which have had May Day—Child Health Day as their inspiration. Communities working together for a single project have acquired a spirit of effective cooperation, and have discovered its values as well as its difficulties. They have found that working together was time-saving, money saving, and sometimes life-saving.

At this time, more than ever, with reduced appropriations and budgets, individuals and groups should come together to meet the desperate needs of the hour.

The Conference of State and Provincial Health Authorities of North America, the body which last year assumed the responsibility for the national conduct of Child Health Day, believes that adequate care for babies and for expectant and nursing mothers must be the foundation on which to build a nation of healthy children. They will therefore use this year the slogan, Mothers and Babies First. The health officers are fighting to maintain the public health measures which they believe most necessary to protect infant and maternal health. Popular support is needed as never before. In nearly every state the State Chairman for May Day is to be found in the State Board of Health or in the Bureau of Child Hygiene, where such exists. So that, where

Syphilis	48	44	48	39	39	70	49	33	36

Remarks: No cases of Asiatic cholera, glanders, plague or yellow fever during the past seven years.

it seems desirable, the opportunity exists for promulgating a state-wide May Day program covering some particular aspect of child health

More often, however communities decide on their own local projects, which may cover babyhood, the preschool age or the child at school, or all three. Whatever the project, National Child Health Day is becoming year by year more productive of practical results

From the first year of its observance May Day—Child Health Day has had for its symbol the daisy. There is something in the milk white beauty of its petals which recalls the innocence of childhood. Those who know this flower will recognize also its vitality. Drought cannot kill it, storms do not harm it. We want this vitality for our children, we want so to build that, as Calvin Coolidge once said "America may produce men and women worthy of our standards of citizenship. This can only be done by joint action. No home, no school, no public or private agency can take on the whole task. Team work and understanding of all are needed to reach the goal of May Day—children whole and healthy in body, mind and spirit.

MORTALITY RATES

Telegraphic returns from 86 cities with a total population of thirty-seven millions for the week ending March 24 indicate a mortality rate of 12.5 against a rate of 11.7 for the corresponding week of last year. The highest rate (22.4) appears for Hartford, Conn. and the lowest (4.7) for Yonkers, N. Y. The highest infant mortality rate (13.0) appears for Peoria, Ill. and the lowest for Evansville, Ind., Miami, Fla., Salt Lake City, Utah, Schenectady, N. Y., Somerville, Mass., South Bend, Ind., and Tacoma, Wash., which reported no infant mortality.

The annual rate for 86 cities is 12.7 for the twelve weeks of 1934 as against a rate of 12.3 for the corresponding period of the previous year—*Bureau of the Census*

The mortality rate for February and March 1934 is now above that of the corresponding months of 1933

CORRESPONDENCE

A VERDICT AGAINST A PHYSICIAN IN A CASE OF SYMPATHETIC OPHTHALMIA WITH COMPLETE LOSS OF VISION

Editor *The New England Journal of Medicine*

The above-mentioned case deserves the attention of the medical profession and the public for reasons which I will presently discuss.

The history of the case is as follows:

On July 13, 1927, a boy of 15 was struck in the right eye by a piece of steel (2 mm. by 1 mm.) which was hammered off an automobile wheel rim. The boy went home and applied cold compresses

On the following afternoon he called at the office of an oculist who, according to the latter's statement, recommended that he go to a hospital. This statement was denied by the plaintiff. On July 16 the boy called at my office accompanied by a gentleman. I saw a small prolapse of the iris in the left eye, a traumatic cataract and an irritation of the eye with photophobia and lachrymation.

Not knowing whether the piece of steel had penetrated into the eye, whether it was there or in the orbit, I advised that the boy be taken to the Massachusetts Eye and Ear Infirmary immediately, emphasizing the danger which might threaten the other eye in case they did not obey my directions. The boy could count fingers at a near distance with the injured eye. The left eye was in perfect condition.

There was no question in my mind that, if there was a piece of steel in the eye, and attempts to remove it were unsuccessful, the right eye should be removed in order to prevent a sympathetic ophthalmia. As the latter occurs usually not before the third week, there was plenty of time to take care of the case and prevent total blindness. The injured eye would not be of much use anyway, taking into consideration the damage already done.

On the same day (sixteenth) the patient entered the Eye Infirmary where an x-ray was taken showing the piece of steel near the optic nerve. That same day and also on the following days several unsuccessful attempts to remove the piece of steel with a giant magnet were made and on July 20, a week after the accident, an attempt to remove the piece of steel through an incision and introduction into the eye of a small magnet ended in failure. On July 23 the relatives were advised to give permission for removal of the right eye and on the twenty-sixth the boy was discharged, such permission being denied.

At that time (July 26) neither symptoms of sympathetic inflammation nor even those of sympathetic irritation of the left eye were recorded. During the first week of August the boy was seen by another oculist who diagnosed sympathetic ophthalmia and removed the injured eye but the case resulted in complete blindness.

Is the first oculist who saw the patient on July 14 to blame for the total blindness of the patient?

The oculist of the Eye Infirmary who was in charge of the case and I answered in the negative while the oculist called by the plaintiff answered in a manner which could convey the impression that the delay of two days might have been essential.

No one can deny that the physician who saw the patient on July 14 would have acted more wisely if he had insisted on sending the boy to a hospital despite the objections of the patient or his relative. Few of us if any do not make mistakes or omissions. The point in question is whether the patient's blindness is the accused physician's, nobody's or somebody else's fault.

The lawyer for the plaintiff tried to show that

struck a deeper note Each year new groups have realized that they had a contribution to make Steadily from May Day to May Day, communities have come to understand that teamwork for child health is for the best interests of children

Of all the values of May Day—Child Health Day, perhaps the greatest is the opportunity it presents to enlist the active interest of groups which might otherwise not give the subject of child health any particular thought, and to draw them into the general program

The spirit of cooperation, be it local or state-wide, has been fostered by the activities which have had May Day—Child Health Day as their inspiration Communities working together for a single project have acquired a spirit of effective coöperation, and have discovered its values as well as its difficulties They have found that working together was time-saving, money saving, and sometimes life-saving

At this time, more than ever, with reduced appropriations and budgets, individuals and groups should come together to meet the desperate needs of the hour

The Conference of State and Provincial Health Authorities of North America, the body which last year assumed the responsibility for the national conduct of Child Health Day, believes that adequate care for babies and for expectant and nursing mothers must be the foundation on which to build a nation of healthy children They will therefore use this year the slogan, Mothers and Babies First. The health officers are fighting to maintain the public health measures which they believe most necessary to protect infant and maternal health Popular support is needed as never before In nearly every state the State Chairman for May Day is to be found in the State Board of Health or in the Bureau of Child Hygiene, where such exists So that, where

Remarks No cases of Asiatic cholera, glanders, plague or yellow fever during the past seven years

fever of 102° On April 5 a rash said to be characteristic of measles appeared. At this time the patient complained of pain in the right lower quadrant, aggravated by lying on the right side. The pain persisted. On April 7 she vomited twice. The appetite remained good until April 11 when nausea and vomiting occurred. On April 15 the pain became more severe. She was admitted to the surgical service on April 16, acutely ill and with a well-defined suprapubic mass about four inches in diameter. The mass was also palpable on rectal examination and was very tender. An appendix abscess was drained soon after admission. A part of the appendix and a concretion were found free in the abscess. The colon bacillus was recovered on culture. Convalescence was satisfactory and she was discharged on May 9. She returned on July 31, 1933 and an incisional hernia was repaired. The rest of the appendix was removed. She was discharged August 15.

D B, No 170224 was admitted to the Isolation Building on April 21 1933. For five weeks there had been anorexia occasional nausea and mild attacks of pain in the right lower quadrant. Four days before admission there was photophobia and fever. The day before admission a typical rash appeared. Sharp pain in the right lower quadrant followed by vomiting occurred. The temperature was 103°. On admission, a measles rash was present and there were tenderness and muscle spasm. Immediate operation was done by Dr W E Ladd and an acutely inflamed appendix, wrapped in omentum which covered an appendiceal abscess, was removed. There was some free fluid in the peritoneal cavity and one drain was introduced. Convalescence was gratifying and she was discharged home in the care of a local physician on April 30.

J McM. Framingham Union Hospital No 21942 became ill February 12 1934. A typical measles rash was noted February 16. Beginning February 20 there was generalized abdominal discomfort which persisted. He vomited several times on February 20 and there was diarrhea for the four succeeding days. Between February 24 and March 2 he appeared to improve. Fever and tachycardia which had been present were lessened. On March 2 the temperature rose and he complained of right sided abdominal pain. On March 4 the temperature was 103° pulse rate 120 and the child seemed quite ill. There was tenderness and muscle spasm in the right flank and right lateral aspect of the abdomen. The tenderness was most acute at McBurney's point about which an indefinite mass was palpable. On March 5 operation was performed and an appendix abscess drained. Convalescence was very smooth and he was discharged March 22.

L M Framingham Union Hospital (Number unsigned) was well on March 18. On March 19 there was vomiting diarrhea with mucus and a temperature rising rapidly to 105°. The diarrhea persisted. On March 21 the rash was noted. On March 24 he began to complain of abdominal pain which persist

ed and was paroxysmal. It was confined to the lower abdomen. At times he became distended and a rectal tube gave relief. On March 26 the rash disappeared but abdominal pain, diarrhea, and fever as high as 101° persisted. There was no vomiting. This morning (March 31) the temperature was 99.2° but had been 103° during the night. There was a well-defined midline mass about six inches in diameter extending from the symphysis pubis to the umbilicus. Maximum tenderness and resistance was noted about two inches below and to the left of the umbilicus. The mass was easily felt by rectum. Operation was performed today through a left rectus incision and a very large abscess drained. The appendix was not seen or felt, but the abscess had the characteristics of one of appendiceal origin.

Personal observation of five cases of appendicitis and measles two occurring within a month and in a single community seems more than a coincidence. In addition I have been told of two similar instances, one now in the Children's Hospital, and one additional case in Framingham.

This experience indicates that those gastro-intestinal symptoms associated with measles and variously termed enteritis, ileo-colitis and colitis, be given critical study with the possibility of acute appendicitis in mind.

Yours very truly,

HENRY W HUDSON JR., M.D.

66 Commonwealth Avenue, Boston, Mass

MEASLES AND TUBERCULOSIS

April 2 1934

Editor, The New England Journal of Medicine

Apocryphos of the recent and widespread epidemic of measles in this state, it occurs to me that it is well to direct attention again to the danger of pulmonary tuberculosis as a sequela of measles.

There has been valuable work done in the survey of school children for the early detection of pulmonary tuberculosis and I believe the general practitioner can draw a lesson from that survey which together with other studies shows that the juvenile type of pulmonary tuberculosis can best be detected in its earliest stages by the skin test and a roentgenologic study of satisfactory plates of the chest.

Since a positive skin test does not indicate the location of the infection, it seems to me that only the x-ray plates are necessary primarily for the diagnosis which if positive may be corroborated by other clinical measures and allow of the earliest medical supervision. If the child is in the border line class he can be better directed under the phy

during the first two days an infection and sepsis occurred. What does one mean by the words "infection and sepsis" in the eye? As I see things it means suppuration. But there was no pus in this case. And if pus had resulted because of the delay, it would have been very beneficial in this case, as panophthalmitis usually does not cause sympathetic ophthalmia. The piece of steel, which penetrated into the posterior sclera near the optic nerve, must have been hot and sterile. What took place was a peculiar plastic iridocyclitis with a consequent sympathetic ophthalmia, the cause of which is not known. Meller described lately a case in which notwithstanding the fact that a splinter of steel was removed immediately, a sympathetic ophthalmia developed in the other eye in six weeks after the injury. Crisp in his editorial in the March, 1933 issue of the *American Journal of Ophthalmology* said "The determination of its (sympathetic ophthalmia) etiology has long been counted among the seeming impossibilities of medical science."

This type of inflammation may result from injury other than a penetrating wound. I had a case in which a small boy after a fall developed a detachment of the retina in one eye with no visible injury to the latter. It resulted in an iridocyclitis with a consecutive sympathetic irritation of the other eye.

Therefore, as yet it is proper to speak of a peculiar plastic inflammation which tends to spread to the other eye, and the cause of which is unknown. The words "infection and sepsis" befuddled the issue and conveyed a wrong impression to the jury.

Even the timely removal of an injured eye (before sympathetic ophthalmia has started) in rare cases does not prevent sympathetic ophthalmia since the latter has been recorded as late as 53 days after the removal of the injured eye. An oculist cannot help knowing that blindness in this case might have been due to the delay in the removal of the injured eye rather than to the delay in the removal of the piece of steel.

The accused physician was made a scapegoat. The jury rendered a verdict against the physician in the sum of \$22,000.

On appeal of the physician, the judge set aside the verdict of the jury and ordered a new trial. The physician decided to settle the case out of court, which he did, and closed the case.

This trial shows the weak points in court proceedings against physicians accused of malpractice.

In order to avoid decisions based on a wrong evaluation of facts it would be advisable, in my opinion to amend the court practice in such a way:

1. The jury in such cases should include at least one physician and
2. The decision should be taken by a majority vote so that the jurymen physician could not block the decision.

Besides, as suits for malpractice in some cases may have their origin in a careless remark of an

other physician who happened to come in touch with the case, the physicians connected with the case should not be allowed to testify. The court should appoint experts, whose authority is beyond a reasonable doubt, to state and evaluate the facts.

Yours truly,

O R LOURIE, M.D.

Boston, Mass

APPENDICITIS AND MEASLES

March 31, 1934

Editor, *New England Journal of Medicine*,

The prevalence of measles in Eastern Massachusetts, now reaching epidemic proportions, suggests the desirability of calling attention to acute appendicitis as a complication of, or coexisting with, measles.

Available texts of pathology and of pediatrics discuss the respiratory and aural complications, but on hurried examination were not found to include a discussion of this complication.

Accurate data concerning the incidence were not found. However, Thenebe, Hirschberg and Cinci in the *Archives of Pediatrics* for January, 1933 report six cases in a group of 371 cases of measles admitted to the Hartford Isolation Hospital. Five cases were operated on subsequent to admission and one was admitted after operation in another hospital. All were proved cases. There were no deaths. The incidence of 1.6 per cent is high because uncomplicated cases are not so frequently hospitalized. These authors found little literature on the subject. The first report they found was by Williams of Boston, in 1912. They quote E. C. Smith of the Haynes Memorial Hospital as saying the complication is not rare.

The following five case summaries lend weight to this belief and the fact that two have been seen within the last month and in one community indicates that consideration is pertinent.

D. S. (Children's Hospital No. 146439) complained of headache on February 9, 1931, and had cough, conjunctivitis and fever of 102.5°. These persisted and a characteristic measles rash appeared on the third day. He then complained of pain to the right of the umbilicus. The pain persisted and was of a dull character. There was irregular fever reaching 103°. He was admitted to the private ward on February 20, acutely ill with fever of 103° and a tender firm mass in the right flank. On February 22, a large retrocecal appendix abscess was drained. The appendix was not removed. The colon bacillus was recovered from a culture. Convalescence was uneventful and he was discharged on March 12. He returned on May 15 and appendicectomy was performed the following day. The appendix was scarred, attenuated, and adherent lateral to the cecum. He was discharged in good condition May 25.

E. W., No. 3147869 on April 3, 1931, had a chill and

tended the Central Institute of Pittsfield, Me., for his preliminary education and later was graduated from the Medical School of Maine (Bowdoin) in 1888. He married Miss Abbie Tarr of Etna, Me. His first practice was in Burnham, Me., and later in Plymouth Me. In 1896 he came to Lawrence, Mass. and did special work on eye, ear and throat, until his death on February 18, 1934, from coronary sclerosis following an illness of two days.

In 1896 fellowship in the Massachusetts Medical Society was taken and he served as Councilor, Censor and President of the Essex North District Medical Society. Following the passage of the original Workmen's Compensation Act in this state in 1911 which was passed without the advice or consent of the physicians of Massachusetts, the many inequalities of its provisions as related to the medical profession were early recognized. Through the earnest efforts of Dr. Merrill and other members of the Essex North District Society and other District Societies, a campaign was inaugurated which culminated in giving to the profession after spirited activity some improvements in the administration of the act, the most important being the adoption of the principle recognizing the right of the injured employee to choose his own physician.

Dr. Merrill was elected to the Medical Staff of the Lawrence General Hospital in 1900 and served as senior ophthalmic and antral surgeon until his recent resignation and election to the consulting staff.

Dr. Merrill accepted the office of trustee of the Lawrence Industrial School, was a member of the local Chamber of Commerce, a director of the Lawrence Tuberculosis League, a member of the Sanitary Milk Commission and consulting physician to the Danvers State Hospital.

Dr. Merrill held fellowship in the American Medical Association and was an active member of the Lawrence Medical Club for many years and a Fellow of the American College of Surgeons. He was a Mason and received the Knights Templar degree.

Among the more advanced special societies which enrolled the doctor's name were the American Academy of Ophthalmology and Oto-Laryngology, New England Ophthalmological Society and the New England Otological Society.

His survivors are his widow and two sons, one of whom Urban Howe Merrill, M.D., was associated with his father and will carry on his special work in the quarters which have so long known the senior Dr. Merrill. The second son is Ivan C. Merrill of Maine.

Dr. Merrill accepted a commission in the Medical Department of the Army in the World War and was called into service January 1, 1918, at the age of 53 and served during the war in New Mexico and at Camp Devens and was discharged as Captain following the armistice.

Our deceased friend was an example of a real

physician. His interest in his profession was marked by constant attendance and participation in all meetings to which he held allegiance. His strong support of all activities of value to physicians and patients was practical and valuable. In his professional work the humble station in life of any patient was no bar to his receiving proper treatment. Dr. Merrill possessed a good mind, was a quick thinker, was dignified and dependable. His great kindness to the younger men of the profession was acknowledged by all. His character and nature were such that the better one knew him, the more he was respected. It can be properly said of Dr. Merrill that he fulfilled every duty to his family, his profession and his fellowmen.

We the members of the Lawrence Medical Club do hereby express our feelings of great sorrow at the loss of our friend, companion and fellow physician, Dr. William H. Merrill.

GEORGE B. SARGENT, M.D.,

NOTICE

LAWRENCE CANCER CLINIC

Lawrence, Mass.,
March 31, 1934

To the Physicians of the North Half of Essex County

Dear Doctor:

The regular Lawrence Cancer Clinic to be held at Lawrence General Hospital, 1 Garden Street, Lawrence, upon Tuesday, April 17, at 10:00 A.M., will be a Demonstration Clinic with Channing C. Simmons, M.D., of Boston, Associate in Surgery at Harvard University Medical School, acting Surgeon in Chief at Collis P. Huntington Memorial Hospital and member of the Cancer Commission of Harvard University, Boston, present as consultant. You are invited to accompany any of your patients whom you desire shall have this service or to send them with a note and a report will be returned to you. This service is gratis. Your attendance at the Clinic is always welcome.

This Clinic is endorsed by the Committee on Postgraduate Instruction of the Massachusetts Medical Society.

AN EXPENSIVE DISEASE

April 3, 1934

Editor, *The New England Journal of Medicine*,

A letter recently published in the *Journal* from Dr J Harper Blaisdell relative to the costs for tuberculous patients in the town of Winchster, Mass., prompted me to investigate the costs for similar service in my home town of Mansfield, Mass

I am given the following figures

The assessment received by the Selectmen of Mansfield from the County Commissioners of Bristol County for the support of the T B Hospital at Attleboro, Mass., for the year of 1933 was \$4712.02

The records show that during the year the town had one patient in the hospital for thirty five days for which \$46.80 was paid and another patient for seventy two days for which a check for \$94.90 was paid

The total bill, therefore, for the town for 1933 was \$4,853.72 for a total hospitalization of one hundred and seven days, which is at the rate of \$317.52 per week or \$45.36 per day or \$1.89 for each hour of every twenty four hours that the patients of the town were under treatment

Naturally, it makes me feel that the town of Winchester got out of the situation rather easily as compared with Mansfield

But seriously, does it not make one view the increased tendency toward State Medicine with a good deal of apprehension?

Yours very truly,

FRANK H. DUNBAR, M.D.

86 Rumford Avenue,
Mansfield, Mass

RECENT DEATHS

COOK—SNOW PARKER FREEMAN COOK, M.D., of 111 Main Street, Gloucester died at the Addison Gilbert Hospital, April 6 1934. Dr Cook was born in Liverpool, N.S., in 1861 and his premedical education was acquired at the Acadia College, Wolfville, N.S. He graduated in medicine from the University of Pennsylvania School of Medicine in 1886 and practiced in Gloucester for about forty years.

Dr Cook joined the Massachusetts Medical Society in 1893. His practice was devoted to diseases of the nose, ear and throat. He was a member of

the Tyrian Lodge of Masons and a director of the Cape Ann Savings Bank

TOWNSEND—CHARLES WENDELL TOWNSEND, M.D., of Boston and Ipswich, died in Boston on April 3, 1934, at the age of seventy five years. Born in Boston, the son of Thomas Davis Townsend and Frances Barnard Smith Townsend, he prepared for college at Noble's School and was graduated from Harvard College in 1881 and from Harvard Medical School in 1885. He had in the past served on the staffs of the Massachusetts General, the Boston Lying In and the Children's Hospitals, and the Seashore Home for Sick Children at Winthrop.

Dr Townsend was best known, however, as an ornithologist, having written many books and papers on the birds of various sections of the country. Surviving him are his son, Charles Townsend, of Boston, three daughters, Miss Gertrude Townsend of Boston, Mrs Hale Sutherland of Bethlehem, Pennsylvania, and Mrs Wendell Taber of Boston, a brother, William S. Townsend, and three grandchildren.

KIRK—LUCY A. KIRK, M.D., of 637 Dudley Street, Dorchester died at her home on April 5 1934. She was born in Dorchester, Massachusetts, in 1859, the daughter of Joseph and Eleanor Hall (Stimpson). Kirk. She was graduated from the Training School for Nurses at the Hartford Connecticut, Hospital in 1883 and received her M.D. degree from the Boston University Medical School in 1893. She served on the staff of the Boston Homoeopathic Dispensary from 1894 to 1902 and was a member of the Massachusetts Homoeopathic Medical Society, the Massachusetts Surgical and Gynecological Society and the American Institute of Homoeopathy. Dr Kirk is survived by a sister, Miss Eleanor Hubbard Kirk.

O'TOOLE—THOMAS HENRY O'TOOLE, M.D., died at his home in Norwood on April 4 1934 at the age of sixty two. Born in Clinton he moved to Philadelphia where he received his early education, later being graduated from Johns Hopkins University, and Jefferson Medical College of Philadelphia in 1897.

Dr O'Toole settled in Norwood thirty five years ago for the practice of medicine.

He joined the Massachusetts Medical Society in 1922 and was a Fellow of the American Medical Association. He was a member of the Norwood Lodge of Elks, the Knights of Columbus and the Foresters.

He is survived by his widow, a daughter, Mrs Marie Heffernan, and a son, Dr Thomas H. O'Toole of Norwood.

OBITUARY

WILLIAM HOWE MERRILL, M.D.

William Howe Merrill, M.D. of Lawrence, Mass., was born in Newport, Me. April 3, 1864 the son of Phineas and Elizabeth (George) Merrill. He at

an increased demand are (a) blood loss due to hemorrhage or fetal requirement (b) infections, (c) chemical agents, (d) idiopathic elements such as are seen in hemolytic jaundice, erythroblastemia, and sicklelema. The demand may be normal but the marrow hypoactive as in (a) specific malnutrition with deficiency of liver extract, iron, or vitamin C, (b) toxic inhibition by infections and azotemia as well as chemical agents.

In his consideration of the anemia of pregnancy the speaker stated that it was rare to find pregnant women with less than 45 per cent hemoglobin and less than 25 million erythrocytes. In a long series of cases he found less than 74 per cent hemoglobin in 82 per cent of the ward patients while 68 per cent of the private patients exhibited a like deficiency.

The anemia of pregnancy is a hypochromic anemia with low color index due to a deficiency of iron resulting from low intake, failure to utilize, or loss of iron by hemorrhage or to the fetus. The gastric acidity very frequently becomes reduced to zero in 50 per cent of the cases and all have some diminution of this factor.

The hemoglobin is not made up for months or years after the pregnancy unless active therapy is instituted. The lower the percentage of hemoglobin the more liable the patient is to develop complications because of poor health due to the anemia.

Diet is important, for the speaker found that in those patients with normal acidity and a good diet, only 5 per cent showed an anemia, those with low acid and a poor diet were anemic in 12 per cent of the cases, while with no acid and a good diet 18 per cent showed definite evidence of hemoglobin lack.

The infants of women with lowered hemoglobin have as much of this material at birth as those of normal women, but such children do not store enough iron for the first year of life. Those children whose mothers are treated before the birth of the infants are as well off as the children of normal women.

Abnormal leukocyte counts are often seen in infants of mothers with low hemoglobin. During pregnancy there is an added requirement of blood building material which the mother must provide for the fetus. Consequently her diet should be adequate in protein and iron-containing foods.

Treatment of the disease may be carried on through the use of 90 grains of iron and ammonium citrate daily. In those women with an acidity cure may be brought about by the administration of five ounces of normal gastric juice with beef steak daily in addition to the iron. If pernicious anemia accompanies the hypochromic anemia 10 cc. of liver extract should be given intramuscularly twice weekly in conjunction with the iron. The infants of anemic mothers should have one-sixth of the dose of iron taken by the mother.

In closing Dr. Strauss placed particular emphasis

on the fact that the anemia of pregnancy may be prevented by the daily administration of 30 grains of iron and ammonium citrate during the entire course of the pregnancy.

FAULKNER HOSPITAL CLINICAL MEETINGS

On Thursday afternoon, April 5, 1934, at 5 00 P.M. the regular monthly meeting of the Staff of the Faulkner Hospital was held at the hospital.

Two of the cases which had come to autopsy during the month were discussed.

One was a case of pulmonary tuberculosis, which was complicated by difficulty in swallowing. This was pronounced, but still food was able to enter the stomach. X-ray studies showed a very definite obstruction throughout the lower half of the esophagus. The roentgenologist felt that this obstruction was more from pressure outside and ulceration in the wall of the esophagus than from neoplasm. It was felt by others that a neoplasm of the esophagus was more likely as it was quite unusual for a tubercular process in the mediastinum to obstruct the esophagus. The evidence of activity of the pulmonary tuberculosis increased and the patient died. At autopsy there was an extensive tubercular process in the lungs which was spreading and presumably caused death. Surrounding the esophagus there was what amounted to a cold abscess which had invaded the wall of the esophagus. There was no evidence of neoplasm.

The other case was one in which there were threatening abdominal symptoms which progressed rapidly in the course of two days with the development of a tender mass in the right upper quadrant and a leucocytosis. It was felt that the only chance for the patient was an exploration although the outlook appeared dubious. At exploration evidence of bleeding into the mesentery of the upper intestinal tract and throughout the tissues surrounding the pancreas and duodenum was evident. The patient died shortly after the operation and a leaking aneurysm of the abdominal aorta was found.

As Dr. Young was forced to be absent from town, the discussion about gallbladder problems was not given but in place of that Dr. Edward D. Churchill gave a most interesting talk on "Recent Advances in Thoracic Surgery." He discussed the two conditions in which surgery of the lung has made distinct advances, namely, chronic bronchiectasis and cancer of the lung. He called attention to the fact that there are two types of bronchiectasis, one in which there is diffuse bronchiectasis scattered generally throughout both lungs. In these cases surgery is of no value. The other type consists in a localization of the bronchiectasis in one lobe. In these cases it is possible to remove the infected lobe. These cases in which the bronchiectasis is localized in one lobe usually present one of two sets of symptoms. In one case there is a profuse foul sputum without much tendency to bleed; in the other type there is not so much sputum but a tendency for repeated

REPORTS AND NOTICES OF MEETINGS

THE NORFOLK DISTRICT MEDICAL SOCIETY

A meeting of the Norfolk District Medical Society was held on Tuesday evening, January 30, 1934, at 8 15 P.M. in Roxbury Temple with Dr. Alexander S. Begg presiding. The guest speakers were Dr. William Dameshek of the Beth Israel Hospital, Boston, and Dr. Maurice B. Strauss of the Boston City Hospital.

Dr. Dameshek's topic was "Certain Disorders of the White Blood Cells" and Dr. Strauss discussed the "Etiology of the Anemias."

In speaking of the origin of the blood cells, Dr. Dameshek said that the corpuscular elements in the peripheral blood stream have their origin from three sources. The bone marrow is the chief and most important of these. From it arise all the erythrocytes and platelets, and 70 per cent of the leukocytes. The lymphocytes are produced by the lymph nodes throughout the body, and the reticulo-endothelial system, found in the spleen, liver, lymph nodes and bone marrow, furnishes the monocytes.

The bone marrow white blood cells pass through many stages from the primitive to the mature leukocytes, viz., myeloblast, promyelocyte, myelocyte, young metamyelocyte, band form of metamyelocyte and the polymorphonuclear leukocyte.

The Schilling Hemogram is concerned with the determination of the different forms of polymorphonuclear cells in the peripheral blood stream beginning with the young metamyelocyte and continuing through the band forms and mature "poly." The bone marrow reacts to infection in such a way as to put out as many mature forms as possible. Then band forms appear, followed by still younger forms and, if the infection is very severe, myelocytes get into the peripheral blood stream. In a differential cell count the polys may be subdivided in the Schilling Hemogram and thus the prognostic severity of the infection is determined. Shifts give much more information than the ordinary differential as to the progress of the process. In shifts to the left we see young forms, in those to the right older forms are in evidence. Most infections, especially with pyogenic organisms, act in this way.

Agranulocytosis is a cyclic fall in the white blood cell count due to an intrinsic disorder of the white blood cell forming organs and which may be related in some cases to the menstrual cycle. After the leukocyte count has fallen very low, areas of necrosis appear in the throat and buccal mucous membranes because of lack of resistance. Nucleic acid derivatives have been found to stimulate the bone marrow and are used to treat the disease. Pent nucleotide in 10 cc ampoules is given intramuscularly twice daily. The white count will begin to rise in three to five days and goes up in the course of a week.

The speaker referred to the late reaction of lymphocytes to infection and suggested that the

term infectious lymphocytosis, or better still, glandular fever, be used for the disease now so commonly called infectious mononucleosis.

Monocytosis is seen in subacute and chronic infections such as tuberculosis and lues. In tuberculosis the monocyte-lymphocyte ratio becomes elevated and is of value chiefly in children who are anergic. In adult tuberculosis, however, the Schilling Hemogram has greater prognostic significance.

The proliferative disorders of the white blood cells are termed leukemia or preferably leukosis and may be of two types: leukemic, in which the white count is high, and aleukemic, in which the count is normal or below. Leukosis may be myelogenous, lymphatic or monocytic. Under the term myelosis is included acute leukemia, in which the cells are very immature, and chronic leukemia, in which the cells are more mature and an enlarged spleen is a prominent feature.

Most cases of leukosis seen are of the aleukemic type and have been variously misdiagnosed as

- 1) Obscure anemia or pernicious anemia because of the accompanying anemia which is frequently of the macrocytic type. It does not respond to liver.
- 2) Agranulocytosis, because of the leukopenia which is frequently down to 1000-2000. It does not react to pentnucleotide, however.
- 3) Purpura hemorrhagica, due to the presence of diminished platelets resulting from the destruction of the platelet-forming mechanism and the tendency of the patients to bleed.
- 4) Aplastic anemia, in view of the combination of the anemia, leukopenia, and diminished platelets.

Among the localized disorders may be mentioned the rapidly growing myelosarcoma, lymphosarcoma, and reticulosarcoma.

Referring to the diagnosis in cases presenting as their chief complaint or finding a group of enlarged lymph glands in the neck, the speaker emphasized the importance of a good history with particular attention to such features as itching, sweating, loss of weight, and pallor. This should be followed by a careful physical examination, especial care being devoted to all lymph glands, spleen, liver, supra-cardiac dullness and malignant disease of the sinuses and postpharyngeal area. Chief among the laboratory procedures to be done in such cases are urine for Bence-Jones protein, blood smear, chest x-ray, B.M.R., which is frequently elevated in Hodgkin's disease and lymphatic leukemia and the biopsy which is the most important of all. An occasional case of Hodgkin's disease can be treated successfully by complete surgical removal of cervical lymph glands, provided, of course, there is no disease elsewhere.

Dr. Strauss said that the causation of anemia is related intimately to the blood supply and the demand for it. Among the factors which bring about

NEW ENGLAND HEART ASSOCIATION

The next meeting of the New England Heart Association will be held in the Assembly Room of the House of the Good Samaritan, Monday, April 23, at 8 15 P.M.

All members of the New England Heart Association and interested physicians are invited to attend
PAUL W. EMERSON, M.D. Secretary

GREATER BOSTON MEDICAL SOCIETY

There will be a joint meeting of the Greater Boston Medical Society and the staff of the Beth Israel Hospital.

Time Tuesday April 17 1934 at 8 15 P.M.

Place Beth Israel Hospital, Boston Mass

Speaker Frank H. Laher, M.D. Surgeon in Chief The Laher Clinic Boston

Subject The Management of Cholelithiasis and Biliary Tract Infections

Discussion Harry Linenthal M.D., Maurice E. Barron M.D. Carl Bearnse M.D.

D. B. STEARNS M.D. Secretary

THE NEW ENGLAND ROENTGEN RAY SOCIETY

The next meeting will be held at the Beth Israel Hospital Boston Mass Friday night April 20 1934, at 8 15 P.M.

SCIENTIFIC SESSION

Dr Sammel A. Robins will present the following program

I Roentgenological Changes in the Heart After Total Thyroidectomy 10 Minutes Dr David Davis Dr Herrman L. Blumgart.

II. Protracted Irradiation in Carcinoma of the Larynx. 10 Minutes Dr Harry F. Friedman.

III. Report of Case of Schuller-Christian Disease 10 Minutes Dr Charles Liebman.

IV The Value of Lateral Views of the Rectum 10 Minutes Dr S. William Altman

V Roentgenological Exploration of the Biliary Ducts with Lipiodol. 10 Minutes Dr Louis Hermonson

VI Urethrography 10 Minutes Dr M. Leopold Brodny

VII. Cystography and the Prostate 10 Minutes Dr Samuel A. Robins

Three minutes will be allowed for discussion on each paper

The usual dinner will be held at the Harvard Club

ISAAC GERBER, M.D. President

201 Waterman Street, Providence R. I.

SOCIETY MEETINGS, CONGRESSES AND CONFERENCES

April 12—Massachusetts Tuberculosis League will hold its annual meeting at the Hotel Statler Boston beginning at 11 A.M. in Parlor B on the mezzanine floor.

April 12—Massachusetts General Hospital will hold a Staff Clinical Meeting in the Moseley Memorial Building at 8 15 P.M.

April 13—William Harvey Society will meet in the auditorium of the Beth Israel Hospital at 8 P.M.

April 13—Massachusetts Memorial Hospitals. See page 828.

April 13, 20 and 27—Salmon Memorial Lectures. See page 443 issue of February 22.

April 14—New England Association of the Johns Hopkins Alumni will meet at the University Club Boston Dinner at 7 P.M.

April 16—Boston Medical History Club. See page 828.

April 16—Boston University School of Medicine to Conduct a Clinical Meeting at Boston City Hospital in the Cheever Amphitheatre at 11 o'clock.

April 16 20—The American College of Physicians will hold its Eighteenth Annual Clinical Session in Chicago at the Palmer House. For information write Mr. E. R. Loveland, Executive Secretary, 133-135 South 36th Street, Philadelphia Pa.

April 17—South End Medical Club will meet at the office of the Boston Tuberculosis Association 554 Columbus Avenue Boston at 12 noon.

April 17—Lawrence Cancer Clinic. See page 828.

April 17—Greater Boston Medical Society. See notice elsewhere on this page.

April 17—New England Ophthalmological Society. See page 828.

April 17—Malden Medical Society. See notice above.

April 20—New England Roentgen Ray Society. See notice elsewhere on this page.

April 23—New England Heart Association. See notice elsewhere on this page.

April 23 May 5—Physicians Art Exhibit at the Boston Medical Library 8 Fenway.

April 24—New England Physical Therapy Society. See notice above.

April 27—New England Society of Psychiatry will meet at the Boston State Hospital Dorchester Center Mass. at 1 P.M.

April 30—The American Board of Dermatology and Syphilology Examinations for Certificates. Address Dr. C. Guy Lane 416 Marlboro Street, Boston for details.

May 3—Faulkner Hospital Clinical Meeting. See page 828.

May 14, 15, 16, and 17—Thirtieth Annual Meeting of the National Tuberculosis Association. For details apply to the National Tuberculosis Association, 450 Seventh Avenue New York City.

hemorrhages which may often be serious. In addition to the discomfort which these people are subjected to from the bronchiectasis, there is always the danger of the spreading of the infection to other parts of the lung. He called attention to the value of lipiodol injections as a diagnostic procedure in regard to the operability of the case and emphasized the danger of using lipiodol as a diagnostic procedure in all cases. He reports that lipiodol dropped into the trachea just below the vocal cords is as satisfactory as lipiodol introduced through the bronchoscope. He called attention to the importance of a lateral x-ray of the chest in localizing the lesion. In certain instances postural drainage is helpful in these cases but never cures them. Postural drainage should be explained in detail to the patient. In his experience medicines, vaccines and pneumothorax have never cured the condition. The results of surgery in these cases in which the bronchiectasis has been limited to one lobe have been very gratifying. It is usually not a safe procedure in cases above 40 to 45 years of age. The social aspects of the patient are of importance, because if the patient has no dependents radical surgery is more justifiable than if there are dependents, for although the condition is eventually a fatal disease the patient may live for many years.

He then described the technique of operation calling attention to the fact that first a phrenicectomy is done, then an operation to remove the adhesions around the involved lobe and scarring of the rest of the pleura on that side, and finally the third stage of the operation in which the lobe is removed. Dr. Churchill has never seen a phrenicectomy produce a cure, he has seen the second stage of the operation cause distinct improvement, but in practically all cases the third stage is indicated.

In regard to cancer of the lung he reported that there are definite cases on record in which a whole lung has been excised with success and therefore we can no longer say that cancer of the lung is a fatal disease but must make a careful study of each case of cancer of the lung from the point of view of whether it is operable.

The next meeting will be held at the Faulkner Hospital on Thursday afternoon May 3, 1934, at 5 00 P M. In addition to the usual clinical pathological conference on the cases which have come to autopsy during the month, Dr. William W. Howell will give a short discourse on "The Infant's and Child's Resistance." All physicians who are interested are cordially invited.

HARVARD MEDICAL SOCIETY

POSTPONEMENT OF MEETING

The meeting of the Harvard Medical Society scheduled for April 24, to be addressed by Dr. James C. White has been postponed to May 8. Notice with title will appear later.

JOHN HOMANS, M D, *Secretary*

NEW ENGLAND SURGICAL SOCIETY

CANCER OF THE BREAST END-RESULTS*

Massachusetts General Hospital 1921, 1922, and 1923

BY ROBERT B. GREENOUGH, M.D.,† AND GRANTLEY W. TAYLOR, M.D.‡

HEREWITH is presented the fourth of a series of reports on the end-results of treatment of cases of cancer of the breast at the Massachusetts General Hospital covering all cases which entered the Hospital in the calendar years 1921, 1922 and 1923.

The first report of the series¹ was published in 1907, and covered the years 1894 to 1904. In this first report a three-year minimum period was employed, as was customary at that time (although the average period of observation after operation was nearly seven years), and untraced cases were omitted from consideration.

In 1921 another report (Number two) was published² recording the results in the series of cases which entered the hospital in the period from August, 1911 to April, 1914. In this series the five-year minimum period was adopted for end-results. At this time also a formula was devised for recording end-results in cancer cases which was designed to give a complete and balanced account of all cases entering the hospital in a given period, in order that the figures obtained in one hospital might more fairly be compared with those of another institution. This report covered a period during which, by special assignment, almost all cases of breast cancer were allotted to the care of the surgeons who presented the report.

In 1926, a third report was published³ giving the results in the cases of carcinoma of the breast for the years 1918, 1919 and 1920. In this series again a five-year minimum end-result period was employed, but untraced cases were omitted from consideration. In this report the employment of prophylactic x-ray treatment as an adjunct to surgery was discussed, and the significance of the histological grading of breast cancer was presented.

The current report (Number four) covers all of the cases of breast cancer which were admitted to the Massachusetts General Hospital in the calendar years 1921, 1922 and 1923, two

hundred and thirty-eight in number. Twenty-three of these cases were in the private ward and from the attending surgeons, data sufficient for classification and end-results were not obtainable. Nine were reëntries (duplicates) and two cases, although entered as cancer, were proved by pathological examination not to be cancer at all. One case received no treatment and six died of causes other than cancer before the lapse of the five-year period⁴. These cases have been deducted from the 238, leaving 197 cases for study of which 177 were primary cases and 20 recurrent after previous operation.

In the following tables and discussion, the term "Cure" applies to a case which had pathologically proved cancer of the breast and which has shown no evidence of a recurrence for a minimum period of five years after operation. Cases which died within the five-year period without evidence of recurrent disease are omitted as inconclusive. Cases which died after five years without evidence of disease are included as "cures". Cases which died after five years with recurrent disease are classified as failures.

The classification of cases adopted by the American College of Surgeons has certain definite advantages for recording the degree of development of the disease, and the 197 cases of this series have been tabulated in that form.

The No 1 indicates primary cases, No 2 indicates recurrence after radical operation and No 3 indicates recurrence after incomplete operation. The letters indicate the extent of disease, as follows:

- A. Process confined to the breast, axillary nodes not involved.
- B. Axillary nodes doubtful.
- C. Axillary nodes involved.
- D. Supraclavicular nodes involved.
- E. Remote metastases.
- F. Other breast involved.

This tabulation shows five-year "cures" in 29 per cent of all cases entering the hospital. It includes primary and recurrent cases, those treated by operation, whether radical or palliative, and those not operated on at all, a salvage of nearly one in three of all cases. One hundred and seventy-seven primary cases, including advanced and inoperable cases, were

*Read before the New England Surgical Society, September 29, 1933, at Boston.

BOOK REVIEWS

The Health and Turnover of Missionaries By WILLIAM G. LENNOX. Published by the Advisory Committee, New York City. The Methodist Book Concern, 1933. 217 Pages.

Dr. Lennox, who has long been interested in medical missionary work and has spent many years in China, has recently compiled for the Missionary Societies of America a useful statistical study, which now appears in book form. When one realizes that there are more than 29,000 missionaries in foreign

lands and that during the course of a single year nearly \$70,000,000 is expended for the upkeep of this service, there are many problems presented which justify investigation. It is brought out by this study that many missionaries leave their work just at the time when they are becoming valuable to the organization supporting them. In other words, to use the slang of the time, the "turnover" is very high. In order to present the facts regarding this, Dr. Lennox has tabulated and charted statistics covering a period of many years. From the medical point of view, the causes of death from infectious and tropical diseases and the large number of missionaries who withdraw from service on account of functional nervous disease are the outstanding results of the investigation. The author recommends the establishment of a central medical department with full-time physicians who would conduct examinations, direct laboratory work, and handle medical records of all the missionaries for eight or ten of the largest Boards, with offices in New York. By this method it is hoped to control the medical missionary service in a more efficient manner than has been possible in the past.

The Modern Treatment of Syphilis By JOSEPH EARLE MOORE. Published by Charles C. Thomas, Baltimore. 535 Pages. Price \$5.00.

In general, this book provides information in as simple terms as possible as to what can be done for patients with various types of syphilis and as to what results may be expected. It is written largely from a background of the author's own experience, but the work of other investigators has not been neglected. While a thorough review of literature is not attempted, important contributions are utilized, especially those of the Coöperative Clinical Group composed of the chiefs of the syphilis clinics of the University of Pennsylvania, the Mayo Clinic, the University of Michigan, Western Reserve University, Johns Hopkins University and representatives of the United States Public Health Service. Bibliographies of source material follow each chapter.

We have here a detailed and scholarly, yet simple presentation of the best methods of treatment and their attainable results, which should interest general practitioner and specialist, from the pen of a well-known investigator, an able teacher and clinician.

Les Troubles de L'Élimination Urinaire de L'eau By JULES COTTE. Published by Masson et Cie. 260 Pages. Price 32 fr.

This book on the physiologic, pathologic, and clinical study of water elimination in renal disease offers nothing new to the internist. If the author of this work attempted to clarify the maze of contradictory work in this field and apply some of it practically, the reviewer feels that he has surely failed. As a matter of fact, Widal and his associates many years ago reviewed the subject very thoroughly.

for the previous series are presented for comparison

TABLE III

1904 (3 yrs)	1914 (5 yrs)	1920 (5 yrs)	1923 (5 yrs)
16%	32%	30%	36%

It is of interest to note that during the three-year periods ending in 1914 and 1923, Breast Cancer was a special assignment while in the 1904 and 1920 series cases were distributed over the regular surgical services

There were seventeen incomplete or palliative operations in this series with four five-year "cures" or 23 per cent. In fifteen cases no operation was attempted and the patients were given x-ray treatment. None of these patients survived five years. While the fact is already well established it is to be emphasized that nothing short of the complete radical operation can be expected to give the patient the chance to which she is entitled to be cured of cancer of the breast.

The classical measurement of the degree of extension of cancer of the breast is the involvement of the axillary lymph nodes as shown by pathological examination of the tissue. The clinical estimate of axillary involvement is, however, erroneous in a considerable proportion of cases. Thus in this series 16 out of 50 in the 1-A group were thought on clinical examination to have involved axillary nodes which were proved on pathological examination to be free from disease (32%). On the other hand 24 out of 111 (22%) showed no clinical evidence of enlarged nodes although on pathological examination after removal cancer proved to be present.

It is true also that cancer in certain regions of the breast, notably the median hemisphere and the upper inner quadrant, may extend to the internal mammary chain of nodes within the chest or directly to the supraclavicular nodes before reaching those in the axilla. In spite of these inaccuracies, however, the involvement of axillary nodes is still our most valuable measure of the extent of the disease.

In this series there were 50 cases in the 1 A group (axillary nodes not involved) with 31, or 62 per cent five-year cures. There were 111 cases in the 1 C group (axillary nodes involved) with 23, or 21 per cent five-year cures. The six cases in which the supraclavicular nodes were enlarged gave no cures (in spite of one attempt to dissect the supraclavicular region) and the cases of remote metastases and the one case of bilateral involvement were also failures. The postoperative survival of the 1 A and 1 C cases is shown in chart I.

We have some reason to doubt the accuracy of clinical data as regards the duration of cancer of the breast. In the present series of cases

preoperative duration of over two years was arbitrarily reduced to two years. On this basis the average preoperative duration for 107 cases treated by radical operation was found to be 82 months. Of this number 78 were failures with an average preoperative duration of 91 months. There were 29 five-year cures with an average preoperative duration of 57 months. Among the cured cases, however, there were at least three patients who reported a preoperative duration of two years or more. In a previous series (1918-1919-1920) it was found that in 39 cases with greater than the average duration there were 10 cures (26%) while in 52 cases with less than the average duration there were 12 cures (23%). In the present series the average preoperative duration in the

1 A cases (nodes not involved) was 72 months. The cures in this group averaged 62 months' duration and the failures 87 months' duration. The average preoperative duration in the 1 C group (axillary nodes involved) was 87 months. The cures in this group averaged 57 months and the failures 93 months. In view of these figures we must admit that however important the duration of the tumor may be in the individual case its value in group prognosis is limited.

It is frequently suggested that cancer of the breast has a much graver prognosis in young women than in older women. When our cases are divided into two groups, those over 50 years of age and those less than 50 (the approximate mean age of the group) it is found that the cures are respectively 34.5 per cent and 32.8 per cent. In a series as small as this one, the difference is not significant. When the cases are divided into three groups, however, those under 45 years of age, those from 45-60 inclusive, and those over 60, the percentage cures are respectively 22.2 per cent, 40 per cent and 45 per cent. About half the cases fall into the middle group and roughly a quarter each into the young and old groups. These figures therefore do emphasize strikingly the relatively greater gravity of the disease in younger women. The pathological classification of breast can-

2 Recurrent after Radical Operation	11	0	
3 Recurrent after Palliative Operation	9	0	
Total All Entries	197	56	29

There were one hundred and forty-five radical operations in this series, by which is understood the removal of the whole breast, the skin over the breast, both pectoral muscles, the axillary contents to the clavicle, and the deep fascia from sternum to latissimus and from clavicle to epigastrium. These radical operations yielded fifty-two or 36 per cent five year "cures."

The clinical criterion of operability has been a tumor movable on the chest wall with at most small movable axillary metastases. We have gradually narrowed the field of operability in the course of the years covered by these reports. Skin nodules, large or fixed axillary nodes, a swollen arm, and supraclavicular fullness have been recognized as contraindications to operation. Routine preoperative x-ray study of the bones and chest for determination of the presence of remote metastases was not followed in all cases of this series although it has since then come into general use. Care in history and examination of the patient, and clinical alertness in interpreting backache or dyspnea have gradually become more common.

The so-called "inflammatory" type of carcinoma of the breast is now generally recognized as not curable by operation. The development of effective palliative treatment in the form of radiation has made us less willing to recommend operation in poor risk patients. These factors alone even without consideration of such improvements in operative technique as we believe developed prior to this period, should entitle us to show progressive improvement in our cures by operation in successive series of cases. It is probable that with greater attention to these factors, many of the deaths which occur within the first six months after operation could be avoided.

The figures for the percentage of five year "cures" from radical operation in operable cases (1A—1B—1C—A C S Classification)

in general very early cancers, and that the curability is high in this group. Certainly the figures give no ground for supposing that exploration is prejudicial to cure. We are strongly of the belief, however, that exploration or excision of a doubtful breast tumor should never be undertaken unless facilities for a frozen section diagnosis, and for the completion of the radical operation at the same sitting, are available.

In addition to radical operation, 125 cases received either preoperative or postoperative prophylactic x-ray therapy. These cases gave 48 or 38 per cent five-year cures. The 13 cases which did not have x-ray therapy yielded only four, or 31 per cent cures. The relatively small number of cases in the latter group makes this percentage difference of little or no significance.

Only 11 cases received preoperative x-ray therapy, with nine failures and two successes. Seven of these cases also received postoperative x-ray therapy.

Virtually all the x-ray cases were treated either by Dr G. W. Holmes at the Massachusetts General Hospital, or by Dr L. B. Morrison of Boston. During this period Dr Holmes was using a Waite and Bartlett machine 5 milliamperes, 16 inch distance, 3 mm aluminum filter, 80 K.V., later equipped with boosters to yield 200 K.V. Dr Morrison used an Acme machine, 140 K.V., 12 inch distance. For preoperative treatment 1 erythema dose was given. For postoperative treatment usually two erythema doses were given in one series of 12 to 14 weeks.

It is regrettable that opportunity for comparison of similar series with and without prophylactic radiation is not available at this time. With the data available, however, we are forced to admit that prophylactic x-ray treatment gave slightly better five year results in this series than in the previous series and that the improvement in the end-results of this series may well be due in part at least to the more general use of x-ray. It should be noted however, that in the 1918-1919-1920 series the I A cases (glands not involved) formed only 25 per cent of the whole series, while in the present group the percentage of I A cases has risen to 28. Final conclusions in regard to the value of prophylactic x-ray, therefore are scarcely justified from these statistics.

SUMMARY AND CONCLUSIONS

1 A consecutive series of cases of cancer of the breast entering the Massachusetts General Hospital in the years 1921-1922-1923 is reported with the five-year end-results

2 In comparison with previous series, the percentage of five-year cures has gradually increased since 1904. Greater care in estimation of the operability may be expected to increase the percentage of five-year cures.

3 Twenty-nine per cent of all cases entering the hospital are free from disease more than five years and 36 per cent of the cases of radical operation are free from disease more than five years.

4 The extent of the disease as determined by pathological examination of the tissues removed at operation is of the greatest importance in prognosis.

5 The preoperative duration of the tumor as recorded by the patient is of relatively little value in prognosis.

6 Cancer of the breast in young women is less curable than cancer in older women.

7 The histological grading of the degree of malignancy of the tumor is of great importance in prognosis, but it must be considered in connection with the extent of the disease and with other factors affecting the prognosis.

8 Tumors pathologically of high-grade malignancy metastasize early to the axillary lymph nodes and elsewhere.

9 Exploratory incision or excision of a breast tumor, properly performed, does not prejudice the chance of cure.

10 Prophylactic x-ray therapy was employed almost as a routine in this series and the improved results in the series may be in part due to this treatment.

11 Further reduction of the mortality from cancer of the breast depends today chiefly upon further education of the public and of the profession to regard seriously and to treat promptly and properly any abnormality of the breast.

NOTE. The writers acknowledge gratefully the assistance of Dr Charles E. Dumas of Boston in reviewing the radiation therapy given in these cases and of Dr Harry F. Hartwell in the study and grading of the pathological material.

cer as to the degree of malignancy as indicated by the cellular architecture and histology has been followed out in this series of cases. The criteria on which the grading was done have been described elsewhere.⁵ Since the original report we have been obliged to give consideration to an additional factor, "infiltration." This is a condition found occasionally even in cases of relatively pure adenocarcinoma or medullary growth, in which the tumor cells in one place or another have broken out from their elsewhere typical conformation and have infiltrated the fat and fibrous tissue in the neighborhood in columns of a more scirrhous type. This appearance we regard as a marked step in de-differentiation, and thus an indication of high malignancy. The present series yielded 122 cases of radical operations with known five-year results, of which the microscopic slides were obtainable for review. The examination of these slides was made by Dr H F Hartwell and Dr R B Greenough. The grading was done without knowledge of the end-results, and in only five cases were there serious differences of opinion between the two observers, and these were readily composed on further study and discussion.

The results are shown in table IV, which presents also the percentages of cures from the previous series for comparison.

TABLE IV

DEGREE OF MALIGNANCY IN RELATION TO CURES

	Cases	Cures	Per Cent	'18, '19 '20 Series Per Cent
Axilla Not Involved				
Grade I	8	8	100	82
Grade II	29	17	59	43
Grade III	5	0	0	0
Axilla Involved				
Grade I	1	1	100	50
Grade II	42	13	31	31
Grade III	37	1	3	0

The grade of malignancy in relation to the duration of postoperative life is shown in chart II.

In this series the number of low-grade tumors is lower than in the previous series. The percentages, however, are not materially different. One notable exception exists to the general rule, namely, the single case in the Grade III, I C group which is alive and well, now nine years after operation. This case has been reviewed and discussed, but shows so great a degree of pleomorphism and so complete a degree of de-differentiation that it is impossible to grade it other than as a highly malignant tumor.

The application of this classification of the degree of malignancy of a breast cancer to the prognosis of the individual case must be made

with considerable reservation. We must recognize that every case of breast cancer is capable of causing the death of the patient. Again the extent of the disease is of the greatest significance. Other things being equal, however, we may say that a tumor of low grade malignancy does not extend so widely nor so promptly from the point of origin, and thus the opportunity for successful removal is greater than in the middle group, and far, far greater than in tumors of high malignancy. That 42 out of 122, or 34 per cent of this series fell in the high-grade group indicates that a very considerable number of cases of cancer of the breast are still beyond the hope of surgical relief. However, unless our present idea of the origin of cancer as a local process is incorrect, there

is no reason why earlier and earlier recognition of the disease should not give us more and more cures even in the cases of high grade malignancy.

The significance of the grading for prognosis may be considered also from the viewpoint of preoperative duration of the disease. It will be noted that all the Grade I cases were cured and that with one exception all the Grade III cases were failures. The average preoperative duration for both groups was the same, namely eight months. The Grade II cases without axillary involvement presented an average duration of 5.3 months in the cured cases, and of eight months in the failures. The Grade II cases with axillary involvement averaged 4.6 months in the cured cases and 10.3 months in the failures.

Axillary metastases were present at the time of operation in 11 per cent of Grade I cases, 70 per cent of Grade II cases, and 90 per cent of Grade III cases.

An attempt was made to determine the possible danger of exploratory incision in cases of doubtful diagnosis. Definite exploration of the tumor was made in 27 cases, including a few in which several days elapsed between simple mastectomy and radical operation. This group presented 15 cures (55.5%). It should be realized that cases in which exploration is indicated are

There were 179 operations performed by 22 surgeons, 90 were performed by two men. Only two other surgeons performed more than eight operations during the three years.

RADICAL OPERATION—By radical operation is meant the removal of the breast with all the overlying skin, the deep fascia, the contents of the axilla and both pectoral muscles. A modified transverse axillary incision was usually employed and the longitudinal incision carried well down toward the umbilicus in order to remove the lymphatics from this region. A portion of the anterior sheath of the rectus muscle was usually removed. The skin incision was beveled to remove a large amount of subcutaneous tis-

sue. The wounds were usually closed with some tension and drained. Secondary skin grafts were rarely necessary. We have been impressed by the relatively few cases of skin recurrence when the subcutaneous lymphatics were removed and we believe it is unnecessary to excise a very large amount of skin if the incision is made in this manner. Slight sepsis and sloughing of the edge of the skin flap occurred in many instances but rarely necessitated closure by secondary skin graft.

INCOMPLETE OPERATION—This term has been employed to cover any operative procedure short of the radical operation. We consider it justifiable in certain elderly people in poor physical condition, or as a palliative procedure to remove a sloughing tumor if the local growth cannot be controlled by radiation.

The 190 primary cases in which the disease was limited to the breast or breast and axilla may be subdivided as follows (table 3).

It will be noted that of the 179 cases operated upon the end-result is known in 176. Excluding the case in which no pathological examination of the specimen was made, the cases that died of other causes within five years, without recurrence

of disease and the patients that refused operation there remain 167 cases suitable for study. The cases dying of intercurrent disease less than five years after operation have been carefully reviewed and it is improbable that death was caused by a remote metastases. In 66 or 40 per

cent the axillary glands were not involved microscopically while in 101 the disease had extended into the axilla.

RESULTS—Of the total of 167 primary cases in which the disease was confined to the breast and axilla, 69 are known to be living and free from disease five or more years after operation (40.9%). This is to be compared with the figures in previous reports (Table 4).

TABLE 4
COMPARISON OF RESULTS OF TREATMENT

Period	Per Cent Cures
1894-1904 (3 years)	19%
1911-1914 (5)	27
1918-1920 (5)	30
1921-1923 (5)	35
1924-1926 (5)	41

There was one postoperative death of pulmonary embolism on the 18th day.

Of the 167 cases a radical operation was performed on 158 and an incomplete operation on nine. Of the nine patients in whom an incomplete operation was performed five are living without disease, two of these were 75 years of age, and in two a small area of carcinoma was found microscopically after a simple amputation for what was believed to be cystic disease. The fifth case was one of medium malignancy in which cancer was found in the glands removed from the lower portion of the axilla. Three of

CANCER OF THE BREAST END-RESULTS*

Massachusetts General Hospital 1924, 1925, and 1926

BY CHANNING C. SIMMONS, M.D.,† GRANTLEY W. TAYLOR, M.D.,† AND RICHARD H. WALLACE, M.D.†

THE following report is based on the cases of carcinoma of the breast admitted to the Massachusetts General Hospital in both the private pavilion and the general wards for the three-year period, 1924-1925-1926. It is made for comparison with similar reports prepared by Dr. Simmons and Dr. Greenough.

In 1907, the cases of cancer of the breast admitted to the hospital from 1894 to 1904, 613 in number, were collected and the results of treatment studied on a three-year basis¹.

In 1921, the results of treatment of 115 cases observed in the three-year period 1911 to 1914 were reported on a five-year basis².

In 1926, the results of treatment of the cases seen in the hospital in the three-year period 1918-1920 were studied. In this series the cases treated in the private pavilion were included³.

The results of treatment of the cases seen in

Taken as a whole the figures show some improvement and suggest that patients are seeking advice for a tumor of the breast at an earlier date.

Many statistical papers on the etiology of the disease have been published and in the following only those factors which have a direct bearing on the choice of treatment and prognosis will be considered. In studying the cases the histories were posted on the abstract record sheets prepared by the American College of Surgeons and the classification adopted by the College was employed.

The term "cure" is applied to cases living without evidence of disease five or more years after operation. No case is considered as a cure unless the diagnosis was confirmed microscopically. A minimum of five years from the time of operation has elapsed in all cases. The average time after operation was seven years while many cases have been followed for nine years. Eight cases (10.5%) living at the end of five years are known to have died later of metastases and are considered as failures. It is probable that a few others now living will also die of this disease. The greater number of the living cases were examined personally by some member of the hospital staff or their local physician, although in a few instances it was necessary to rely on a letter from the patient.

Untraced cases are considered as having died of cancer. This may not seem quite fair for it has been found that, in this community at least, any case which cannot be traced is usually living. We believe, however, that if the cases are treated in this manner the figures are less open to criticism.

OPERABILITY—It is impossible to determine with any degree of accuracy the percentage of operability. The cases operated upon in the private ward were, obviously, not referred to the hospital unless operable. On the other hand, many incurable patients were hospitalized in order that they might receive high voltage x-ray treatment.

Apparent arithmetical errors may be noted in certain of the tables. We believe these have all been satisfactorily accounted for but to avoid confusion the reasons have not been given in the individual table.

During the three-year period 238 cases were admitted to the hospital. These cases may be divided as follows (table 2).

This discussion will be confined to the primary operable cases, i.e., the 1-A and 1-C groups of the classification of the American College of Surgeons.

TABLE 1

EXTENT OF DISEASE—OPERABLE CASES

	No of Cases	Axillary Glands Not Involved
1894-1904	353	33%
1911-1913	62	31
1918-1920	99	30
1921-1923	148	28
1924-1926	168	41

the three-year period 1921-1923 have been collected by Dr. Greenough⁴.

This series has been studied to determine if there has been any improvement in the results of treatment. During the period 1910 to 1920 the radical operation was more generally performed, and in this series the patient had the advantage of x-ray treatment combined with surgery, although radiation treatment at this time was admittedly much inferior to that given at the present day. An active campaign of public education was also instituted by the American Society for the Control of Cancer and the Massachusetts Department of Public Health in 1924.

In all of the earlier series the ratio of cases without involvement of the axillary glands to those in which the lymph nodes were diseased remained about the same. This series shows a slightly larger proportion of early cases (Table 1).

*Read before the New England Surgical Society, September 29, 1933, at Boston.

cent the axillary glands were not involved microscopically, while in 101 the disease had extended into the axilla.

RESULTS—Of the total of 167 primary cases in which the disease was confined to the breast and axilla, 69 are known to be living and free from disease five or more years after operation (40.9%). This is to be compared with the figures in previous reports (Table 4).

TABLE 4
COMPARISON OF RESULTS OF TREATMENT

Period	Per Cent Cures
1894-1904 (3 years)	19%
1911-1914 (5)	27
1918-1920 (5)	30
1921-1923 (5)	35
1924-1926 (5)	41

There was one postoperative death of pulmonary embolism on the 18th day.

Of the 167 cases a radical operation was performed on 158, and an incomplete operation on nine. Of the nine patients in whom an incomplete operation was performed five are living without disease, two of these were 75 years of age, and in two a small area of carcinoma was found microscopically after a simple amputation for what was believed to be cystic disease. The fifth case was one of medium malignancy in which cancer was found in the glands removed from the lower portion of the axilla. Three of

the cases that died of recurrence and two of those living received prophylactic postoperative high voltage x-ray treatment

EXTENT OF DISEASE AND RESULTS—The operable primary cases in which an attempt to cure by surgery was made may be divided into those with and those without involvement of the axillary glands. There were 66 cases in which the disease was confined to the breast with 43 cures or 64 per cent, and 101 cases in which the axilla was involved with 26 cures or 26 per cent (Table 5)

TABLE 5
CURES AND EXTENT OF DISEASE

	Cases	Cures	Per Cent Cures
Axillary glands not malignant	66	43	64%
Axillary glands cancerous	101	26	26

The results are shown in graphic form in table 6 which gives the percentage of cases living at yearly intervals. In making these graphs the three cases in which the result is not known are omitted

TABLE 6
PERCENTAGE OF CURES AT YEARLY INTERVALS

PATHOLOGY AND RESULTS—In most cases the specimens were available for review and examined by Dr. H. F. Hartwell, surgical pathologist at the Massachusetts General Hospital, Dr. Greenough or Dr. Simmons.

The cases were divided into three degrees of malignancy: low, medium and high, and the results of treatment of these three groups com-

pared. The following points were considered in determining the degree of malignancy:

- (1) The degree of differentiation of the cells, that is the tendency of the tumor cells to form glands and the evidence of secretory activity, as shown by the presence of vacuoles in the protoplasm.
- (2) The uniformity in size and general appearance of the cells and nucleus, and the number of mitotic figures.
- (3) The tendency of the tumor to infiltrate.

A tumor composed of cells of uniform size and shape, containing vacuoles and having a marked adenomatous arrangement was considered as being of low malignancy. One in which there was little or no tendency to glandular formation and in which the cells infiltrated the surrounding tissues, varied in size, and presented pleomorphic nuclei with many mitotic figures was considered as being of high malignancy. Comparing the pathological index of malignancy as determined in this manner with the results, it was found that there was a very distinct relation between the two (Table 7).

TABLE 7
PATHOLOGICAL INDEX OF MALIGNANCY AND CURES

	Cases	Cures	Per Cent Cures
Grade 1	27	22	80%
2	89	34	39
3	47	13	27.7

Taking into consideration both the pathological index of malignancy and the extent of the disease the results were as follows (tables 8 and 9).

TABLE 8
PATHOLOGICAL INDEX OF MALIGNANCY AND CURES

Axilla Not Involved			
	Cases	Cures	Per Cent Cures
Grade 1	20	18	90%
2	26	19	58
3	8	4	50

TABLE 9
PATHOLOGICAL INDEX OF MALIGNANCY AND CURES

Axillary Involvement			
	Cases	Cures	Per Cent Cures
Grade 1	7	4	57%
2	53	13	24
3	39	9	23

This is shown in graphic form in tables 10-11-12, in which the percentage of patients living at yearly intervals is given for the different grades. In tables 11 and 12 the results are given for the

groups with and without axillary involvement separately

In cancer of low malignancy the axillary

TABLE 10

PATHOLOGICAL INDEX OF MALIGNANCY AND PERCENTAGE OF CURES AT YEARLY INTERVALS

TABLE 11

PATHOLOGICAL INDEX OF MALIGNANCY AND PERCENTAGE OF CURES AT YEARLY INTERVALS—DISEASE LIMITED TO THE BREAST

glands were involved in about one-third of the cases, in cancer of medium malignancy one-half

and if the tumor was of high malignancy two-thirds

TABLE 12

PATHOLOGICAL INDEX OF MALIGNANCY AND PERCENTAGE OF CURES AT YEARLY INTERVALS—AXILLA INVOLVED

TABLE 13

PATHOLOGICAL INDEX OF MALIGNANCY AND AXILLARY INVOLVEMENT

	Axillary Glands Not Cancerous	Axillary Glands Cancerous
Grade 1	65%	35%
2	45%	55%
3	30%	70%

It will be noted that the results of operation for cancer of low malignancy with diseased axillary glands were better than those of cancer of medium malignancy in which the disease was confined to the breast

From a study of the results of this group of cases we believe that the pathological index of malignancy is of definite aid in determining the prognosis in the individual case, although several other factors must also be taken into consideration. Certain striking exceptions that cannot yet be explained occur, and the personal equation of the pathologist also enters into the grading of any group of cases

AGE AND RESULTS OF TREATMENT (Data on 155 cases)—The ages of the patients varied between 32 and 81, and contrary to the statement often made there were an appreciable number of cures in patients under 40 years of age. Of the 17 cases between the ages of 30 and 40, six were living without disease five or more years after oper-

ation In all of these cases the disease was limited to the breast, however (Table 14.)

TABLE 14
AGES AND RESULTS

Age	Cases	Cures	Per Cent Cures
31-40	17	6	34
41-50	53	21	40
51-60	50	22	44
61-70	26	11	40
71-80	9	3	33
Totals	155	63	

The cases were then divided into two groups Of 70 cases less than 50 years of age 27 or 39 per cent were cured, while of 85 patients over 50 years of age 35 were cured or 40 per cent These figures suggest that although the diffuse cancer seen in lactating breasts in younger women is usually incurable by surgery, other forms do occur which are not so highly malignant These two types can often be recognized clinically Of the six cases under 40 years of age cured, two were pathologically of low malignancy, one of medium and three of high malignancy It will be noted in the table that the percentage of cures varied relatively little in the different decades when the small number of cases in any one bracket is considered

Taking into consideration the pathological index of malignancy and the age of the patients operated upon, it was found that there was a slightly larger number of cases of the more malignant forms in patients between the ages of 30 and 40, but the figures were not striking The actual percentage of cases of high malignancy occurring in this decade may be somewhat larger than is indicated by the figures, as the inoperable cases were, obviously, not referred to the private ward for operation, and if seen as out-patients in the general hospital were referred directly to the x-ray department for treatment (Table 15)

TABLE 15

PATHOLOGICAL INDEX OF MALIGNANCY AND AGE

Ages	No of Cases	Grade 1	Grade 2	Grade 3
31-40	17	12%	52%	35%
41-50	53	19%	54%	26%
51-60	50	16%	48%	36%
61-70	26	19%	66%	15%
71-80	9	11%	55%	33%
Totals	155	16.8%	54.2%	29%

OPERATION AND RADIATION—RESULTS (Data on 164 Cases) — Prophylactic radiation treatment as given in the years 1924-1925-1926 would be considered inadequate when judged by present-

day standards Eight hundred r were given in 3 doses with the high voltage machine, that is 200 kv The exposures were made at 50 cm distance and filtered by $\frac{1}{2}$ mm of copper and 4 mm aluminum Three portals were used as follows one 20 x 20 cm over the chest anterior, one 15 x 15 cm in the axilla and one 15 x 15 cm to the back to include the supraclavicular space

In studying the cases, those that did not report regularly are excluded Ninety patients received what at that time was considered sufficient prophylactic x-ray treatment This was given before operation in 12 instances, and in 78 after operation Of the 90 cases, 31 are living, 34 per cent, while of the 74 patients who received no prophylactic x-ray treatment 41 are living, or 54 per cent To exclude the error which might be due to the possibility that only the more advanced cases received prophylactic treatment, the cases in which the axillary glands showed no disease were considered separately Of 18 cases without axillary disease that received radiation treatment 11 were cured, 61 per cent, while of 44 cases in the same group who did not receive treatment 30 were cured or 68 per cent In the patients in whom the glands were diseased, 70 received radiation treatment of which 18 were cured or 26 per cent, and, of the 28 cases that did not receive treatment in this group, seven were cured or 25 per cent The results are shown in table 16 It will be noted that the figures in both of these groups are practically the same It must, therefore, be concluded that prophylactic radiation treatment as given in the years 1924-1925-1926 to this group of cases did not influence the results of operation

TABLE 16

SURGICAL CURES AND PROPHYLACTIC RADIATION

	A Ray Given			No X Ray		
	Cases	Cures	Per Cent	Cases	Cures	Per Cent
Axilla not involved	18	11	61%	44	30	68%
Axilla diseased	70	18	26%	28	7	25%

The duration of life after operation in these two groups of cases is shown graphically in tables 17 and 18

Accurate data in regard to the effect of x-ray in preventing local recurrences and to the prolongation of life and relief of symptoms in recurrent cases are unsatisfactory, for if all the factors that govern the prognosis are taken into consideration there remain such a small number of cases in each group that it is unfair to draw conclusions The general impression obtained, however, was that prophylactic radiation did not prevent local recurrence In cases of recurrent cancer, radiation treatment made the patient more comfortable and prolonged life

EXPLORATORY INCISION—In many cases the tumors were seen at an early stage of the disease

TABLE 17

DURATION OF LIFE WITH AND WITHOUT PROPHYLACTIC RADIATION—DISEASE LIMITED TO THE BREAST

TABLE 18

DURATION OF LIFE WITH AND WITHOUT PROPHYLACTIC RADIATION—DISEASE LIMITED TO BREAST AND AXILLA

and an exploratory incision was made into the growth to verify the diagnosis, before performing the radical operation. In most instances,

an incision was made directly into the tumor a specimen removed for examination and the wound packed with a sponge wet in alcohol or formalin. The radical operation was then performed immediately. Thirty-three cases were explored before operation in this manner of which 21 were cured or 65 per cent. In 127 instances the tumor was not explored, and of these cases 45 or 35.4 per cent were cured.

It is obvious that the early cases favorable for surgical cure and in which the diagnosis was in doubt were explored, while in the more advanced cases a radical operation was performed without investigation of the primary tumor. It seems fair to assume, however, from these figures that a carefully performed biopsy followed by immediate radical operation does not tend to disseminate the disease.

In two instances the tumor of the breast was excised at another institution, found to be cancer and the patient referred to the Massachusetts General Hospital where a radical operation was performed five and fourteen days later. One of these was a case of low malignancy in which the disease was confined to the breast and the operation resulted in a cure. The other was a case of high malignancy with axillary involvement and the patient died of recurrence. We have felt that a biopsy performed in this manner was a dangerous procedure as it disseminated the disease and that the radical operation performed later rarely resulted in a cure.

DURATION OF DISEASE—GRADE OF MALIGNANCY AND RESULTS (Data on 139 Cases)—As in previous series of cases it was found that the duration of the tumor before operation had little relation to the percentage of cures. This is interpreted to mean that the cures were obtained in the slowly growing forms of the disease. Of 94 cases of less than six months' duration, 41 or 43.5 per cent were cured while in 49 cases of over six months' duration 21 or 43 per cent were cured. If the pathological index of malignancy was considered as well the figures are far from conclusive but suggest that a larger proportion of the cases of high malignancy considered suitable for operation were seen within six months of the onset of the disease. It is to be inferred that the average case of high malignancy of over six months' duration was considered inoperable (Table 19).

TABLE 19

DURATION OF TUMOR AND PATHOLOGY			
Grade		Less Than 6 Months	Over 6 Months

SUMMARY

- (1) The five-year end-results of the cases of carcinoma of the breast operated upon

at the Massachusetts General Hospital in both the private pavilion and the general wards are given

- (2) There were 167 cases in which an attempt at surgical cure was made, and the result is known in 164 instances. Where the result is not known the case is presumed to have died of cancer.
- (3) Sixty-nine cases or 40.9 per cent are living without evidence of disease from five to nine years after operation.
- (4) In the 66 cases in which the disease was confined to the breast 43 or 64 per cent are living.
- (5) Of the 101 cases in which the disease extended to the axillary glands 26 or 26 per cent are living.
- (6) The pathological index of malignancy as determined by the amount of differentiation of the cells in the microscopic specimen was found to be one of the important factors governing the prognosis.
- (7) Cancer of low malignancy curable by surgery occurs frequently in women under 40 years of age.
- (8) Prophylactic x-ray treatment as given in 1924-1925-1926 to this group of cases apparently had no effect in preventing recurrence.
- (9) The impression obtained from the study of recurrent cases, however, was that radiation treatment made this group of patients more comfortable and prolonged life.
- (10) Exploratory incision if carefully performed does not disseminate the disease.
- (11) Something over 11 per cent of the cases living without evidence of disease 5 years after operation will subsequently die of recurrence.

DISCUSSION

DR. CARL MERRILL ROBINSON, Portland, Maine*
Mr. President and Members of the Society—Just 48 hours before I left for Boston, I noticed by the program that I am expected to discuss the statistical papers of Dr. Greenough and Dr. Simmons. You have my apology for my inadequate and almost ex tempore discussion.

*Read by Dr. William H. Bradford.

At the Maine General Hospital during the five years previous to last June, there were 203 breast cases admitted. A much simplified classification of them is as follows:

Abscess	12
Adenomatous growths all types	26
Mastitis and cystic disease	58
Fibroma	2
Lipoma	2
Dermoid cyst	1
Simple hypertrophy	3
Sarcoma	2
Paget's disease	1
Duct cancer	3
Metastatic cancer	3
Primary cancer	90

203

Approximately 50 per cent of all breast cases admitted were malignant. End results are not available as our tumor and follow-up clinics are just getting under way.

My personal records, 1926-1932, show 45 cases of cancer of the breast operated upon and a considerable number of others referred for radiation. In January of this year, I had reports from 36 of these. Twenty-three were living and symptom free, six over five years, five over four years, and ten over two years. Three died of other causes, ten died presumably of cancer. There were six deaths within two years of operation from cancer of liver, bone metastasis or general carcinomatosis but I did not find any record of local recurrence in these cases. These few cases show very definitely the distinction between operability and curability by operation. They show our helplessness in detecting early metastasis either by x-ray or physical examination. I am assuming that metastasis had taken place before operation as I have no evidence of local recurrence as the source of general dissemination.

In going over the records of the x-ray therapy department with Dr. Thaxter, I find a distressingly large number of cases sent in for postoperative radiation with bone and lung metastases, so obvious, that they should have been easily detected by x-ray before operation. Operation on this type of case, other than as a palliative procedure, brings disrepute to surgery and helps to send curable patients to the various cults and types of quackery.

We are very sure that our end results at the Maine General are definitely improving since we have insisted on careful x-ray study before the decision on operability is made.

I must report one tragic case in which we tried so hard to do the right thing. A life-long friend of mine and the wife of a doctor consulted me about five years ago at the age of 47 for a small nodule in the upper outer quadrant of the left breast. Her husband had known of it for two years but considered it of no importance. Both breasts were large and heavy and had always produced an overabundance of milk during her four periods of lactation. The general impression was bilateral cystic disease. No other distinct nodules were felt and no glands palpable. Removal of the growth showed it to be encapsulated and grossly benign. Frozen section report was adenoma but because of the presence of cystic disease about the tumor, pathologists advised simple mastectomy which was done. Study of the breast tissue removed showed adenocarcinoma. We had obviously done inadequate surgery for cancer of the breast.

The slides were seen by Dr. Greenough and Dr. Hartwell. We were advised to subject the patient to immediate x-ray treatment and to do a radical operation after several months. The dissection of

the axilla was done about three months after the original mastectomy and showed a single gland with evidence of invasion. The functional result was excellent. The patient resumed all her activities and gained weight.

Shortly after her first radiation, the remaining breast showed some diminution in size and the gland tissue seemed peculiarly close to the skin. The breast, which had been removed, showed cystic disease and we assumed that a similar process was present in the remaining breast, with involution hastened possibly by radiation. However, we sent her to Dr Greenough for consultation. Should a simple mastectomy be done? Dr Greenough felt that it was unnecessary. Repeated examinations physical and x-ray, showed no change in her condition.

A few months ago she presented herself to me in the best of health but somewhat concerned because a friend of hers had told her that fixation of the skin over the breast meant cancer. The process was distinctly more definite than on previous examination and the whole breast felt firmer but no definite tumor could be felt. Again we called for help and Dr Greenough advised surgery. Radical operation of the breast was done and a small hard cancer was found with much fibrosis of the whole breast. Pathological examination showed carcinoma of the duct type with a single gland in the axilla showing invasion. Again she had x-ray and to date is doing well. Here we have two distinct types of cancer in opposite breasts both, of which showed cystic disease. Were both of these tumors primary?

I have enjoyed very much the papers by Dr Greenough and Dr Simmons. They bring to mind more clearly than ever how difficult it is to keep a proper perspective on a problem like cancer in a small hospital with relatively few cases in any one series.

DR. LUCIUS C. KINGMAN, Providence, R. I. These breast tumors are clinically queer. There was a patient in the office yesterday for a routine examination on whom I did a radical breast operation seventeen years ago and from whom I removed a skin nodule about three inches from the original scar one year ago. That nodule was adenocarcinoma. Where had the cells been in the meantime? Where have the cells been all the time that show up in the spine nine years after a radical operation?

As we see the cases clinically about all we can do is to determine whether in that individual case we can get away with an operation. We see a case and we fear to operate on it and we think "What's the use? She will be dead in three months" and she dies of pneumonia nine years later. Another case on which we think we have done a beautiful job, dies of lung metastasis in three months. Until we know the underlying factors of cancer we can't do much more than that.

In regard to radiation I think most of us feel we have to hit the carcinoma with everything we have that may be of benefit. We unfortunately at home in a tumor clinic see a great many cases that are inoperable. These we subject to radiation and we get an occasional case in which, following radiation we can do a palliative operation at least. Under our eyes cancer tissue is affected by radiation. If so before operation it seems reasonable that there must be some effect in some cases following operation.

I am quite in agreement with the first speaker who mentioned axillary involvement probably being a measure of the spread of the disease, not of the age of the disease that it may represent the more active type of carcinoma, not because the patient has neglected it.

I am in even a worse position than Dr Robinson because I didn't have forty-eight hours notice. I knew nothing about the discussion until I arrived here, so I can't inflict you with more figures.

DR. HORACE K. SOWLES, Boston, Mass. I should like to ask Dr Taylor one question in regard to his age group prognosis with apologies to Dr Simmons because I think his tables partially answer the question. It seems to me that given a carcinoma of the breast in a young person the prognosis is not bad merely because that person is young because in the young person the resistance is probably better and if a young person developed the disease it is probably a higher grade malignancy.

It seems to me that, given a hypothetical carcinoma of the breast the prognosis for that individual carcinoma of the breast is just the same whether the patient is twenty-five or seventy-five years of age.

DR. STEPHEN A. MAHONEY, Hallowell, Mass. I see that the title of the paper is "Cancer of the Breast—End Results." Now the question in my mind is when are the end results? Can you simply state when is the end of cancer, in a person who has cancer of the breast?

During the reading of the paper, two cases in my practice came to my mind. Sixteen years ago I operated on a case of cancer of the breast, doing the ordinary radical operation, followed it along for about two years and then the case disappeared. Thirteen years after the operation the patient appeared again in my office with a recurrence at the upper part of the sternum evidently due to a metastasis in the anterior mediastinum. We gave a fatal prognosis. We had come into the possession of some radium at that time and inserted 50 milligrams of radium into the sternum going through it, evidently into the anterior mediastinum. That resulted in an ugly slough at the upper part of the sternum. After two or three months that finally healed.

That was three years ago. That patient we saw last week and we would say that she was cured but the question in our mind is: Is she cured? Are there still cancer cells in that patient that will reappear? So, are there such things as end results in cancer?

In another case that is now under active treatment we operated seven years ago, gave the ordinary after-care following along for about two years and then discharged her as cured. Five years later she reappeared in the office with her side entirely studded with skin cancer, en cuirasse type of recurrence. Under x-ray that has been held in abeyance for the past two years.

Three weeks ago she appeared again in the office with a definite cancer of the opposite breast and we operated on that breast by simple mastectomy but going up into the axilla. She made a good recovery. Is it an end result, after seven years?

The question is when shall we report end results in cancer?

DR. GRANTLEY W. TAYLOR. Dr Robinson and Dr Kingman both emphasized the desirability of very careful pre-operative studies in cases of carcinoma of the breast, in the matter of determination of operability.

Dr Richard Dresser has recently made a study of cases of carcinoma of the breast at the Pondville Hospital with complete skeletal x-rays, with very interesting findings. That study is in process of publication if it has not already been published. The significant finding he brings out, I think, is that ordinarily three x-ray treatments are adequate for determination of the presence of remote metastasis. He has a plate involving the chest, including the

shoulders, and the dorsal spine, and another of the pelvis and he believes we should have the skull plate, on the ground that the skull frequently was the only place showing the osteometastasis. Seven teen per cent of the breast cases showed osteometas tasis with no other evidence of metastasis elsewhere, as contrasted with 14 per cent showing pulmonary metastasis with no metastasis elsewhere.

By taking those three plates, it seems you do all you can to rule out remote disease, always bearing in mind that frequently the patients may have symp toms referable to bone metastasis, especially in the spine, considerably before they will show up by x ray examination.

Dr Sowles raised the question of whether the youth of the patient per se has anything to do with the prognosis. I am sorry if my findings gave that impression. I said cancer in young people ap parently has a poorer prognosis than cancer in older people, I think, and I agree with Dr Simmons in thinking that that is because the more malignant types of growth tend to occur more commonly in younger people and the more benign types in older people. If you could get two equally comparable types as regards their degree of malignancy, one in a young person and one in an old person, the prog nosis in regard to cure would not differ appreciably in those two.

Dr Mahoney perhaps would point out that the young person's prognosis was poorer as she was going to live longer and so would be more likely to develop late recurrence. Specifically in regard to Dr Mahoney's point, I think a real mathematician perhaps could take the chartings which Dr Simmons and I both showed of the survival at intervals after operation in the various groups of cases and plot a curve by which he could tell you what the annual decrement would be after a certain period of time on the basis of a mathematical formula. It would show as Dr Simmons pointed out, that about 11 per cent more cases will die of late disease than have already shown evidence of recurrence at the end of five years. That becomes increasingly a smaller percentage as time goes on.

Of course you can't tell which one of a group of cases will be the one which will carry the residual minute percentage of recurrent disease after the follow up period.

These two extensive studies, although ostensibly five-year studies, Dr Simmons has followed for nine years in many cases, and my chart showed an eight-year determination.

DR. CHANNINO C. SIMMONS. There are certain other points brought out in the study of these cases. It has been impossible to determine the operability as in the general hospital the inoperable cases are weeded out in the Out Patient Department and Tu mor Clinic and are not admitted to the wards. In the private pavilion no case is referred for surgical treatment unless it is operable.

All cases have a radiographic examination made of the chest and bones before operation to rule out the possibility of remote metastases.

Cases in which the diagnosis can only be definite ly established by an exploratory incision are referred to the hospital and I find that my clinical diagnosis is more often incorrect than was formerly the case.

There is an operative mortality of from 1 to 4 per cent. In the series reported there was one death from pulmonary embolus, an operative mor tality of 6 per cent.

Late recurrence, that is recurrence five or more years after operation is relatively common in can cer of the breast. This is not true in cancer of cer tain other organs as, for example, the tongue in which recurrent disease after three years is rare, although a second cancer may develop at some point on the buccal mucosa. It is necessary, how ever to place some time unit and five years has been generally adopted, with the understanding that approximately 15 per cent of the patients living at the expiration of that time will probably develop late recurrences.

Patients with cancer of the breast have been known to live from 15 to 20 years without treat ment after the diagnosis was established. One of the most illuminating papers on this subject was published by Dr E. M. Daland. He followed 100 consecutive cases of cancer of the breast which re ceived no treatment and found 26 per cent living five years from the onset of the disease. It must be understood, however that these patients were liv ing with disease and all died within ten years, while of the cases operated upon, living five years, the greater number are living without disease.

DAIRY SCIENTISTS PERFECT METHOD FOR RECOVERING MILK ALBUMIN FOR BABY FOOD

Scientists of the Federal Bureau of Dairy Indus try have devised a method and a factory scale ap paratus for recovering milk albumin from sweet whey, with the natural properties of the albumin unimpaired. The Bureau estimates that the pow dered albumin can be produced for somewhat less than 50 cents a pound and that its chief value would be as an ingredient of modified infant foods, which commonly retail for about a dollar a pound or for adding to cows milk to make it more suitable for infant feeding.

The albumin of milk resembles somewhat the al bumin of egg and has high nutritive value. Cows milk, which contains less than half as much albumin as human milk, has a tendency to coagulate in large masses which digest slowly in the infant stomach whereas human milk coagulates in the stomach in fine flocks and is easily digested. The addition of the powdered albumin to cow's milk serves not only

to raise the albumin content but to change the phys ical properties of the milk so that when it is acted on by the acids of the infant stomach it is coagu lated into a finely divided curd much like that of human milk.

At present albumin is produced in connection with the manufacture of commercial milk sugar from whey but the albumin has little value because its solubility is destroyed in the separation process. By the new method developed by the Bureau the sugar may be crystallized from concentrated sweet whey, leaving a mother liquor that contains some of the sugar most of the minerals, and all the albumin. This liquor may be dried without affecting the solu bility of the albumin but the salt content of the re sultant powder is so high that it is not suitable for modifying cows milk. The scientists found, how ever, that the greater part of these salts can be re moved without affecting the other constituents by subjecting the mother liquor to electric dialysis be fore drying it and they have devised an apparatus in which this can be done on a factory scale—
Bulletin U. S. Department of Agriculture

OBSERVATIONS ON THE PROBLEM OF
MATERNAL MORTALITY*

BY EDWARD S. BRACKETT, M.D.†

THERE is a rapidly growing literature, both lay and professional, on the subject of Maternal Mortality. The former, while well-intentioned, is usually ill-informed. It lays unwarranted emphasis on comparisons between the published maternal mortality rates of this and foreign countries based on governmental registration of births and deaths. The statement has been made and widely quoted that the United States stands almost if not quite at the bottom of the list of civilized countries in its maternal mortality record and the inference is drawn that the American physician as an obstetrician is about the worst in the world. Writers of professional articles on the subject who should know better also fall into the same error. Euthusiasmatic propagandists for the reduction of maternal mortality to stress a point, quote statistics without careful analysis or intelligent interpretation and thereby defeat their own purpose. The natural reaction of the profession is too often one of defense rather than a determination to find out and remove the causes of maternal mortality which every unprejudiced investigator must admit is unnecessarily high the world over. Kerr¹ states "puerperal mortality and morbidity in this country (England) can be reduced by not less than 40%." The available evidence would indicate that the same is true of maternal mortality in this country. We should, therefore, ignoring invidious and unfair comparisons with the published mortality rates of other countries assiduously apply ourselves to the task of discovering the ultimate causes of puerperal deaths and endeavor to remove the causes found to be preventable. This will be a tedious and humdrum task. No speedy or spectacular results can be anticipated. It means first the careful investigation of individual deaths their intelligent classification and analysis and secondly, a courageous effort to learn the lessons that the facts teach us, put them into practice and by a well-planned campaign of education, lay them before the profession.

A campaign for the reduction of maternal mortality would seem to demand a definition of what constitutes a puerperal death. There is no agreement at the present time even on that point. The Division of Vital Statistics Bureau of the Census Washington² sent 1073 identical copies of selected death certificates to twenty-

four foreign countries for assignment of the causes of death. Replies were received from sixteen countries. Of the 1073 deaths certified only 431 were attributed by all the countries to a puerperal classification without a contributing cause. Of the 642 remaining certificates, the cause of death was assigned to a non-puerperal condition in percentages ranging from 28 to 36.6. Only one country Denmark (28%), assigned fewer deaths to non-puerperal causes than did the United States (11.8%). The interesting fact that Norway (36.6%) and Sweden (33.2%) assigned approximately three times as many of these certified deaths to non-puerperal causes as did the United States somewhat lessens the force of the condemnation of those uninformed propagandists who, to the disparagement of this country have cited Norway and Sweden as shining examples of countries where obstetricians know their business.

These figures show the futility of trying to compare the quality of obstetrical work in one country with that of another if the comparison is based on governmental statistics. While other sources of error in such comparisons could be pointed out this confusion in the classification of certificates showing more than one cause of death is a major factor in the wide discrepancies in the vital statistics of the reporting countries. The Census Bureau's Manual of Joint Causes of Deaths eliminates to a great extent, such discrepancies in statistics as between the states. We may hope that the next Conference on an International List of Causes of Death to meet in 1939 may do as much for international statistics.

However accurate the classification of puerperal deaths may ultimately be the only interest of the obstetrician is in its practical value. All he wishes to know is why there are so many puerperal deaths so that he may take measures to reduce the number of pregnant, parturient and puerperal women who die each year. What particular form the "statistical expression" shall take is of purely academic interest to the practitioner of clinical obstetrics. Whether it be expressed as "the cost in mother's lives in bringing in to the world 1000 live born babies" or as "the risk of maternity in terms of deaths of women of marriageable age for every 1000 pregnancies whether these terminate in live births still births miscarriages or abortions" or "by the difference between the mortality among the child bearing and that of the non-child bearing women"³ must be left to the statistician. From the point of view of the practicing obstetri-

*President's address delivered at the annual meeting of the New England Obstetrical and Gynecological Society November 22, 1932.

†Brackett, Edward S.—Chief of Staff Providence Lying In Hospital. For record and address of author see This Week's Issue page 51.

cian whatever "statistical expression" is chosen and however the deaths are classified the classification should be such that deaths occurring during pregnancy, labor or the puerperium may be studied as a group irrespective of the primary cause of death and irrespective of the month of pregnancy in which death occurred. We all agree that deaths from heart disease in pregnant women or deaths from sepsis following self-induced abortions should not be called "obstetrical deaths" but all of the latter and some of the former are preventable deaths and are therefore of interest to the obstetrician even though they should not be charged against him. What sub-classifications are useful and desirable must be left to the statistician provided he remembers that statistics are but a means to an end and that end is to give useful information.

As soon as a pregnant woman places herself in the hands of a physician, whether he be a general practitioner or a specialist, he becomes responsible for her welfare until she has completed her puerperium. The specialist may share the responsibility if non-obstetrical complications are present or develop, but he cannot escape it. Many of the most serious problems which the physician has to solve have to do with the complications of pregnancy, namely, heart disease, nephritis, pyelitis, tuberculosis and other acute and chronic diseases, both medical and surgical. Many questions as to the treatment of these conditions can be answered only on the basis of statistical studies. Every certificate of death of a pregnant or puerperal woman, even though the cause of death be non-puerperal, should include a statement that the cause of death was a complication of pregnancy.

Death certificates and statistical tables tell us little or nothing. A death certificate giving puerperal sepsis as the cause of death is of little practical value. If we are to draw any conclusions which will be of use in a fight against a high maternal mortality we must know why the patient became infected. Was her resistance lowered by anemia, diabetes or other constitutional disease, was she harboring the gonococcus in her vagina or cervix, was she, or some member of her family, her physician or her nurse a carrier in the upper air passages of *Streptococcus hemolyticus*, did manual dilatation of the cervix or an unnecessary forceps operation or version before dilatation and retraction of the cervix open up wide ports of entry for the anaerobic streptococcus pyogenes already present in the patient's genital tract, did her physician have under his care a septic wound or a case of infectious disease at the time of her delivery, was the patient allowed to go so long in the second stage that she became exhausted, her resistance lowered and her tissue devitalized to the normally non-pathogenic vaginal flora or did

repeated examinations of the vagina transplant the non-pathogenic bacteria of the lower vagina, normally acid, to the normally alkaline cervix where they become pathogenic? When such questions as these are answered we shall know the ultimate causes of puerperal deaths and until we know the ultimate causes we are fighting in the dark. From the clinical standpoint, statistical tables which do not indicate *causes* rather than *results* are useless.

Only a detailed study by a personal interview with the physician while the history of the case is still fresh in his mind can give us any information of real value. Several such studies have been made and others are in progress. While there are many questions which they leave unanswered, they do indicate some points which need to be forcefully presented to the patient, to the medical student, to the hospital resident and to the physician—be he general practitioner, specialist or teacher.

Abortions All surveys so far made and all statistics compiled are in substantial agreement that approximately one fourth of all deaths due to strictly puerperal causes follow abortions. Of these one-third are spontaneous and two thirds are criminal, self-induced or therapeutic. It is somewhat irrelevant, perhaps, but it may be not out of place at this point to remark that self-induced as well as criminal abortions are really infected wounds and should be classified as deaths by violence and not as puerperal deaths. It is estimated that 700,000⁴ abortions occur annually in the United States. The average mortality rate for abortions in the civilized world is 21 per cent. An induced abortion is probably five times as dangerous as a full term delivery. In Magdeburg, Germany, the death rate from sepsis following abortions was seven times greater than that following childbirth. Here is one point of attack on maternal mortality, the education of mothers of the great danger of induced abortions.

Chronic Diseases Complicating Pregnancy About one per cent of all pregnant women have organic heart disease and six to eight per cent of women who die during pregnancy or the puerperium die of heart disease⁴. It is our belief based on our experience in our heart clinic at the Providence Lying-in Hospital that a pregnant woman with heart disease who has never had symptoms suggestive of decompensation can go through pregnancy and labor safely with but moderate limitation of her normal activities. If on the other hand she has edema of the feet and ankles, moisture at the bases of the lungs, shortness of breath on exertion and other signs of beginning decompensation even though she may never have been frankly decompensated, she will if untreated, grow progressively worse and the earlier in pregnancy the symptoms appear the worse the prognosis. If

the patient with this type of heart disease is properly managed by strictly limiting her activities with long periods of rest in bed at the slightest return of symptoms, she will probably do well. On the other hand if there has been decompensation previous to the pregnancy, decompensation will almost surely occur again and it can be prevented only by prolonged rest in bed with proper medication and may require early emptying of the uterus in the most conservative manner possible. The key, then, to the prevention of maternal deaths from heart disease is early recognition of the condition and prompt and adequate treatment. Equally true is it of other diseases complicating pregnancy, tuberculosis, chronic nephritis, hyper- or hypothyroidism, and the toxemias, that only by recognizing them at the earliest possible moment can they be most successfully treated. Here is another weapon of attack in our war on maternal mortality, the constant preaching to the women the necessity of competent medical supervision from the early weeks of pregnancy.

Analgesia I approach the next specific item in the program of education of the patient with some trepidation. In common with all physicians, particularly those past the half-way station in the journey of life, I have a dread of being considered old-fashioned. At the risk of being so considered, I am going to discuss briefly the subject of obstetrical anesthesia and analgesia from the viewpoint of what I consider the attitude the physician should take in discussing it with the patient. Here again the lay press has done its bit to embarrass the conscientious physician. It has done its best to persuade expectant mothers, and the profession too for that matter, that the obstetrician who will not promise the patient a painless labor is a brute. To shift, to some extent the onus of being old-fashioned to more distinguished shoulders I shall quote from the recently published Report of the Sub-committee on Factors and Causes of Fetal Newborn and Maternal Morbidity and Mortality.⁴ This is the report of a subcommittee of President Hoover's White House Conference on Child Health and Protection.

"Pain relief of the parturient is desirable but the problem is essentially different from anesthesia necessary for all operations. Relief given to women in labor must be absolutely devoid of danger to either mother or child. Of the various drugs used for this purpose, administered by mouth, rectum or subcutaneously, the overwhelming majority interfere with uterine activity and many pass into the fetal circulation.

"Necessity for the relief of pain is evident. If, however, the method of pain relief lengthens labor or makes its normal termination less likely, justification of anesthesia is questionable. Again, if the method of pain relief adds an ele-

ment of danger to the child,—such a method is not justifiable.

"By frequent charting of the fetal heart rate and adjustment of the oxygen content of the atmosphere inhaled by the mother, fetal anoxemia can usually be avoided. Whatever the method of pain relief used in obstetrics the tendency to reduce oxygen content of the fetal blood should be remembered and corrective measures instituted when indicated.

"The use of colonic instillation in a mixture of oil recently advocated by Gwathmey is at present experiencing great popularity. The concomitant use of morphine and magnesium sulphate, both extreme muscular relaxants makes the method highly undesirable in normal obstetrics."

All of which implies that many of the techniques more or less widely used demand special training and experience for their safe employment, require constant supervision of trained assistants in anesthesia and are therefore available except in a very limited number of cases, only in hospital practice.

Some years ago in discussing the Gwathmey technique with a prominent obstetrician in a distant city, I asked him what he did if a patient failed to deliver herself as soon as he had expected and the effect of the ether began to wear off. His reply was in effect, that another injection could be given but that as a matter of fact labor had usually progressed so far that he could go ahead and deliver. In other words in that particular clinic they were conducting the labor to suit the anesthetic instead of choosing the anesthetic best suited to the case.

I have singled out for comment the Gwathmey technique not with the thought that it is more or less dangerous than other forms of analgesia but because it has been exploited in the lay press and certain pharmaceutical houses are capitalizing the free advertising it has had and are pushing the sale of the ingredients in handy packages with literature that might tempt one to believe that the only requisite for its safe and successful administration is a right hand strong enough to compress a rubber bulb and insert a hypodermic needle.

What should we tell the patients who do us the honor of placing in our keeping their hopes for a successful labor and a healthy baby when they ask us about this or any other method of mitigating the pains of parturition? I believe we should assert our prerogative of leadership and, instead of servilely following the popular demand of the moment frankly tell them that our first concern is the safety of the mother and the safety of her child. That while we shall do everything within our power to alleviate the pains we will not promise a painless labor if we feel that by doing so we shall run the risk of injuring the mothers or endangering their babies. This subject of relief of pain in labor is one in

which the women are in need of education, not by the lay press, but by their medical advisers.

The problem of the education of medical students is a difficult one and must of necessity be left to the administrative and teaching departments of the medical schools. As one who over a period of some twenty years has had an opportunity in a fairly large lying-in hospital to see the end product of their efforts in the form of internes. I may be able to speak with some knowledge of their qualifications. That they are very poorly equipped to assume the responsibility of guiding any but the normal woman through pregnancy and labor, their teachers well know. Obstetrics is still an art and not a science. No art can be taught. It must be acquired, under instruction to be sure, but still acquired and that too, only by long practice. No medical school can allot to the obstetrical department either time or clinical material sufficient to make it possible to turn out graduates capable of taking care of any but normal obstetrical cases. If that is a fact (and I believe it is generally admitted to be so), the maximum time should be spent on teaching what normal obstetrics is, only such abnormal obstetrics as is required to contrast it with and emphasize the normal and the irreducible minimum on operative obstetrics. I am not conversant enough with the present teaching of obstetrics to know whether this is the policy generally followed. Probably it is.

What has been said of the teaching of students is true only to a lesser degree of the teaching of internes and any but long-term residents. The practice of allowing a short-term resident to decide if and when operative interference is necessary and turning over to him the delivery without adequate supervision is unjust both to the patient and to the resident. The patient has a right to the best judgment and skill available and the resident has a right to counsel and instruction. A year on the most active obstetrical services is too short a time in which to develop either mature obstetrical judgment or manual dexterity.

To deliver by operation, to demonstrate operative technique on a woman who would otherwise deliver herself normally is, in my opinion, reprehensible in the extreme. The injustice to the patient we can, for the purposes of the present discussion, ignore. It is the injustice to the resident of which I am thinking. Such a procedure minimizes in his mind the possible danger of any interference and fails to impress upon him the fact that the most important thing he can learn is not *how* to operate but *when* to operate. This is particularly important if after graduation he is going to practice, not in a hospital, but in his patients' homes, for the man with sound judgment and average manual dexterity will, in the long run, do better obstetrics

than the man with great manual dexterity and poor judgment.

If then, we are to improve our mortality records we must teach the future obstetrician first, what normal labor is, next *when* to operate and last of all *how* to operate.

In considering on what points we, as general practitioners and specialists, need to be educated, it is possible to discuss only a few of the most outstanding of our shortcomings. That we need education is evident. In spite of asep sis, anesthesia and all our modern aids to diagnosis and treatment, we have reduced but little the maternal mortality rate of a hundred years ago and that, too, not because we are dealing with a different type of woman but because we have failed to use wisely or have actually turned against our patients, the weapons which science has placed in our hands. A few years ago I should have resented such a statement but today, being better informed, I believe it to be true.

Prenatal Care Gardiner⁵ in the New York State Survey found that in 30 per cent of the cases investigated, there had been illness which was thought by the attending physician to have possibly affected the outcome. Heart, kidney, and blood diseases accounted for 52 per cent of these. She also found that only 19 per cent of the delivered women had visited a physician before the seventh month.

In another survey it was found that only 54 per cent of the urban white, 39 per cent of the rural white, 20 per cent of the urban colored and 11 per cent of the rural colored who died of puerperal albuminuria and whose condition was reported were in good or even fair condition when they were first seen by a doctor.⁶

Child-bearing is not an isolated experience in a woman's life. Her success or failure in the great adventure of motherhood depends upon the sum of all her past experiences and upon the outcome depends in no small degree her future health and happiness. Not until this thought has become rooted in the subconsciousness of every physician and every pregnant woman should we cease to preach the need of prenatal care.

Sepsis Ninety years after Holmes published his treatise on Contagiousness of Puerperal Fever and over eighty years after Semmelweis reduced his mortality rate in two years from 12.24 per cent to 1.27 per cent (later reduced to .85 per cent), 40 per cent of all puerperal deaths are due to septic infection and of all women who are delivered and die in the last three months of pregnancy 31 per cent die of sepsis.⁶ It has already been indicated that not all cases of puerperal sepsis are caused by infection introduced from without. Any operation in obstetrics is carried out in a field that cannot be

sterilized and to which an occlusive dressing cannot be applied. From the placental wound in the fundus to the skin of the perineum there is no bar to infection by the vaginal flora except the natural resistance of the tissues. The genital tract is traumatized to a greater or less degree in every delivery. The greater the trauma and the lower the resistance of the patient, the greater the danger of infection. If this fact were always in the mind of the operator there would be a reduction in the number of operative procedures and a consequent reduction in deaths from sepsis. It might result, too, in greater care not only in deciding between an operative and a non operative delivery, but also in the choice of the time when the operation should be done. The optimum time for a Caesarian section is before or at the very beginning of labor. The optimum time to apply forceps is after full dilatation and retraction of the cervix and not until the maximum amount of moulding and descent of the head has been accomplished, consistent with the safety of the mother and her child.

Forceps Answers to the White House Conference Questionnaire showed that in 223 hospitals reporting, the incidence of forceps operations ranged from 0.5 per cent to 81.1 per cent.⁴ Such a wide variation in the incidence of any operation is a sad commentary on the present chaotic state of the practice of obstetrics in this country. The average incidence of operative deliveries of all kinds in hospital practice would appear to be between 15 and 20 per cent. It would seem evident that an incidence of forceps deliveries above 10 per cent indicates a belief on the part of the operators that operative deliveries per se, are harmless. In analyzing eight hospital reports I found that the morbidity, based on the standard of each individual hospital was from two and a half to nearly five times as great as that following normal deliveries. Even though we have no concrete evidence to show that maternal mortality following forceps deliveries in well-equipped obstetrical hospitals is much higher than that following spontaneous deliveries it seems certain that a high incidence of operative deliveries with its greatly increased morbidity does cause an occasional death from sepsis and accounts for a vast amount of pelvic pathology following childbirth. If this is true in hospital practice, and it is to be noted that all the figures here quoted are from hospitals, it is undoubtedly true of practice outside of hospitals where it is extremely difficult to preserve a strict aseptic technique.

At the deliveries of 942 white women who died of puerperal sepsis those in charge of the deliveries reported that the technique had been aseptic in 40 per cent, an attempt at asepsis had

been made but had failed in 15 per cent, it had been clean but not aseptic in 36 per cent and dirty in 9 per cent.⁶ In 45 per cent of the cases, therefore, there had not been even an attempt at asepsis. Whatever may be said in defense of the results of "clean" obstetrics in spontaneous home deliveries, nothing can be said in its defense in operative deliveries. It is to be feared that the operative furor which dominates some of the obstetrical centers has an unwholesome effect on the young men who come under its influence and will shortly go into practice in communities where the hospital facilities to which they have become accustomed will not be available. It would probably be safer in home deliveries not to substitute for, but to supplement asepsis with antiseptics.

Caesarian Section In analyzing surveys and hospital reports covering over 43,000 cases I found that the incidence of Caesarian section varied in the different clinics from 5 per cent to 33.6 per cent.⁷⁻⁹ Four other surveys covering 262,853 cases show an incidence of 4.6 per cent to 12.8 per cent. Ill⁹ reports in an analysis of obstetrical work done in Essex County, New Jersey, that, if Newark City Hospital where most of the neglected cases are sent is not included, he found there had been sixty-five deaths in all other hospitals of which 24 or almost 40 per cent followed Caesarian Section. In a survey of Caesarian section in the Cleveland registration area covering five years, published in 1932, Skeel and Jordan¹⁰ found an incidence of 1047 Caesarian sections in 45,650 hospital cases (1 to 44) with a mortality of 7.15 per cent. The incidence in the total cases delivered in that area, both hospital and house was 1 to 90. They also found that the operative or basic mortality was 1.86 per cent. Any operation carrying a mortality rate of 7.15 per cent of which 2.6 per cent is due to the operation per se, and not to the condition for which it is done never should be performed except on definite and serious indications. That at the present time the indications are not definite, an incidence varying from 5 per cent to 14.6 per cent⁴ in hospital practice clearly shows.

Bleeding and Toxemias of Pregnancy It is equally true that there is no unanimity of procedure in the treatment of bleeding and toxemia in late pregnancy. Accouchement forcé (considered by most qualified obstetricians never to be justified) still exacts its toll of maternal deaths. Caesarian section is employed in the treatment of these conditions without proper consideration of the condition of the patient or the type of anesthesia to be employed. In 534 deaths following Caesarian section it was found that the indication for operation was eclampsia in 31 per cent, pre-eclampsia in 9 per cent and uremia in 5 per cent. Placenta praevia and premature separation of the placenta accounted for another 10 per cent. These two conditions,

toxemia and bleeding accounted for 55 per cent of all deaths following Caesarian section. The report of the Study of Maternal Mortality in Fifteen States, says that women with recognized toxemia were kept under observation for long periods and were delivered by emergency Caesarian, women having convulsions were carried long distances to hospitals and operated on immediately on arrival, "both inexcusable procedures."

Let me quote a few published statements of writers on obstetrics

1 "To expect the forces of the uterus and abdomen directed toward the pelvis and in line with the child's body to provide a rotary movement of the fetal head sufficient to turn it 135 degrees is scientifically unsound

"At the thirty-sixth week of pregnancy a posterior position of the occiput is present in 45% of vertex cases examined. Out of 18,500 presentations it was found that the posterior position remained so during labor in 363 cases, this being 1.95%." ¹²

2 "Prolonged labor occurred less frequently in posterior positions than in anterior positions in my service in the same period of time—due to timely interference" ¹³

"In a total of 2160 deliveries there were seven persistent occiput posterior positions. What a pity it is that the world cannot understand that occiput posterior positions are best let alone" ¹⁴

3 "If there are sins of commission in the new school they are many times balanced by the sins of omission in the old school" ¹⁵

"In New York State the gain which has been made by prenatal care, antenatal propaganda, better, cleaner and more conservative obstetrics in the rural districts, is offset in the hospitals of the urban areas by the great increase in operative deliveries and the complications which follow" ¹⁶

4 "It is really impossible to say a great deal about obstetrics in the United States in a short time. There exists such contrast among the obstetricians and their methods that a generalization from what I saw in one or another of the clinics would give an entirely distorted impression. The strongest conservatism is encountered on one side and the greatest radicalism on the other, the latter predominating" ¹⁷

To reduce the present high mortality rate by the education of the profession seems an almost hopeless task until the leaders of the profession are more nearly in accord on the ultimate causes of maternal mortality and the proper treatment of the specific items which keep up the mortality. The advocates of so called modern and old school obstetrics must fight it out. This is not the place to get into that fight but it is perhaps allowable to point what, in my opinion, is the proper attitude while the fight is going on

A radical procedure which may be justified in a modern obstetrical hospital with its rigid

aseptic technique and a swarm of trained assistants always on duty, may be absolutely contraindicated in a private house where neither adequate equipment nor skilled assistants are available. Writers whose experience has been limited to hospital practice seem at times to forget this distinction. The practitioner who does obstetrical work in private houses should never forget it

An obstetrical operation is a surgical operation. No physician can be skilled in all branches of medicine and the practitioner who is not skilled in the art of obstetrics should no more hesitate to call in a consultant who is competent, than he would to call a consultant in any other surgical problem. The consultant should be called in as he is in other branches of surgery not only to perform the operation but to give counsel as to the advisability of interference, the time when interference is demanded and the type of operation to be employed. Too often if a consultant is called at all, the diagnosis is made and his course determined before he has even seen the patient. Such a procedure reduces the consultant to the rôle of a mere mechanic

If an obstetrical problem arises, no qualified consultant is available and the attendant, as so frequently happens in rural practice, must rely on his own resources, he should in choosing his course of action, give due consideration to his own limitations and to the circumstances under which he must work. Prophylactic forceps, in interference, as a routine in occiput posterior positions early in the second stage, have a place, if at all, only in hospital practice

Many obstetrical conditions require for their adequate treatment early hospitalization. Excessive vomiting in early pregnancy, heart complications, toxemia and vaginal bleeding are such conditions. There seems to be a reluctance on the part of the patient to accept and, on the part of the physician to insist upon hospitalization of these conditions until the condition of the patient has become serious. Until this prejudice is overcome, lives will be lost which otherwise might have been saved and to that extent a possible reduction in our maternal mortality rate will be prevented

An obstetrical operation with the possible exception of the extraction of a head already distending the perineum can be done more safely in a hospital than in a private house. An obstetrical operation being a surgical operation, the physician should no more hesitate to insist that his patient go to a hospital for an obstetrical operation than for any other surgical operation

That, as a rule, mortality records in obstetrical departments of general hospitals are higher than in obstetrical hospitals or the home may be due, among other factors, not so much to the danger of air-borne infections as to the fact that

while in the home many considerations may urge delay in operating until there is a definite indication, in a hospital an operation is so easy and, to the unthinking, so safe that a few unqualified and inexperienced men are tempted to interfere unwisely in the normal process of labor and thereby raise the hospital mortality rates.

If what I have said seems pessimistic and fault finding, it is due to the subject I have discussed. If we are to lower the maternal mortality rate we must find our faults and our mistakes before we can correct them and how can one point out faults and not be fault finding? There are many bright spots on the obstetrical horizon. It would be pleasant to point out hospital after hospital where in spite of the grave emergency cases treated, the mortality rate is thirty or less per 10,000 living births, and less than half the country-wide rate. In such hospitals prenatal and postnatal clinics, anesthesia, analgesia, sepsis, forceps, Caesarian section, and all the modern aids to diagnosis and treatment are weapons which are being wisely used. That they are not always wisely used, our mortality rates show. It is their misuse that must be found and exposed and that cannot be done by the piling up of undigested governmental statistics. It can only be done by such studies as have been made in Cleveland and New York (among others) and by the Children's Bureau in Washington where they have gone back of the death returns to the individual cases. No vague campaign of education will do. Specific problems must be solved and specific abuses attacked. And let it not be forgotten that, if the maternal mortality is lowered, it will follow as the day follows the night that the whole standard of obstetrics will be raised.

HEALTH INSURANCE IN ENGLAND

BY SIR HENRY B. BRACKENBURY, M.D.*

TWENTY-ONE years' actual experience of giving and receiving medical advice and treatment under a system of compulsory and contributory national health insurance has had certain definite results both upon the community and upon the medical profession. It must be understood by American readers that the British health insurance system has from its beginning in 1912 included in its medical benefits only the services of a general practitioner in the patient's home or at the doctor's office, that it does not include the services of specialists or hospital care. In addition to medical benefits, cash benefits amounting to a part of the

wages are provided the insured person for a specified period during sickness. All persons employed at manual labor and all other employed persons with annual incomes of less than £250 are legally required to insure under the Act, these employees paying themselves approximately 40 per cent of the total cost, the employer paying about the same amount, and the state the remaining fifth. Over 15 million persons are thus insured under the law and about 15,000 physicians have elected to serve them under its provisions, these physicians ordinarily giving only a part of their time to insurance practice and carrying on private practice also.

On the whole, and leaving out of account for the moment those features of the British system which are not directly concerned with the provi-

Brackenbury Sir Henry B.—Chairman of Council British Medical Association. For record and address of author see "This Week's Issue" page 871.

sion of medical attendance and treatment, the results are beneficial to both and when the expression "on the whole" is used it is not intended to imply that the benefit is just on the right side after nicely balanced consideration, but merely that there are some points of disadvantage which may be set over against an overwhelming preponderance of advantage. That this is so may be judged from the official resolution passed by the Representative Body of the British Medical Association almost without dissent "The measure of success which has attended the experiment of providing medical benefit under the National Health Insurance Acts system has been sufficient to justify the profession in uniting to secure the continuance and improvement of an insurance system." It is some eight years ago that this resolution was passed, but since then it has been endorsed, further resolutions have been adopted pressing for an extension of the system to bodies of persons who are not at present included in it, and by a growing conviction, born of intimate experience, it is acknowledged that any suggestion of the abolition of the scheme would be received by an overwhelming and emphatic protest from the profession and insured population alike.

It is important to emphasize the official and definite character of these and the following expressions of opinion of the medical profession of Great Britain in view of the different and incorrect impressions which have been conveyed to American physicians in certain British "correspondence."

There is a similarly official record of what the medical profession believes to be the general benefits to the community which have been either directly due to, or greatly accelerated by, the National Health Insurance scheme. In the Memorandum of Evidence which the British Medical Association presented to the Royal Commission on National Health Insurance they are thus enumerated: "(a) large numbers, indeed whole classes, of persons are now receiving a real medical attention which they formerly did not receive at all, (b) the number of practitioners in proportion to the population in densely populated areas has increased, (c) the amount and character of the medical attention given is immensely superior to that formerly given in the great majority of clubs, (d) illness is now coming under skilled observation and treatment at an earlier stage than was formerly the case, (e) the work of practitioners has been given a bias towards prevention that was formerly not so marked, (f) clinical records are being provided which may be made of great service in relation to public health and medical research, (g) cooperation among practitioners is being encouraged to an increasing degree, (h) there is now a more marked recognition than formerly of the collective responsibility of the profession to the community in respect of all health matters." These are described as "immense gains," and

further experience has not tended to minimize the value of any of them. The only qualification perhaps required is that, except in a few instances, the authorities have failed to make proper use of the potential value of the clinical records made by practitioners. It may be added that in a number of rural areas it has been found possible to maintain medical attention in places which would otherwise have been left derelict.

Such are some of the main benefits to the community. It is natural to ask also whether there is any evidence, as yet, that the general public health has been enhanced as a result of the working of a National Health Insurance system. This is a question, however, which it is impossible to answer, and probably will always be impossible to answer, with any degree of confidence. There can be but little doubt that during the past twenty-one years, in spite of war and economic calamities, the national health has improved, but it is quite impossible to separate the effects of the medical benefit insurance arrangements from those of other agencies which have contributed, probably more effectively, to such a result—for example, an increase of knowledge of medicine and ancillary sciences, a more effective and widespread public health administration, a much greater realization of the importance of health matters, and education in personal, domestic, and industrial hygiene. It will be realized, however, that the beneficial effects of these other agencies must have been largely augmented and reinforced by the activities of the physician doing insurance work, with out whose services they would have failed of practical application in the homes of the people.

On the other hand, the fact that the provision of cash benefits payable during incapacitating sickness has led to increased claims cannot be taken as indicating any actual deterioration in the general health. It must be borne in mind that the insurance scheme applies to not much more than one third of the population, that the effects of prolonged unemployment and the aftermath of war are still with us, that the propaganda in favor of securing early medical attention and of realizing the importance of minor illness must at first tend to swell the periods of sickness, and that the recent actual prolongation of life almost necessarily increases the total of such periods. These and other purely medical considerations fully account for an increase in sickness claims. Whatever be its actual effects on the public health there is no doubt at all that the insurance scheme has brought to large numbers of persons the advantage and comfort of having a family physician or private medical adviser in whom they have confidence.

The results to the medical profession itself have also been, in general, advantageous. The

system has, in almost all areas and in the case of a large proportion of individual practitioners, increased the feeling that we are colleagues rather than rivals, and has brought about a more conscious relationship between family practice and various aspects of public health service. These are considerable gains. Financially, too, the effects have been beneficial. The aggregate income of members of the profession practicing under the scheme has been largely augmented. There are probably thousands of general medical practitioners today who, without the insurance scheme, would not have been able to earn by the exercise of their profession a sufficient income on which to live. It must not be understood that any money is coming to them through these state insurance arrangements which they have not fully earned. It is the greatly increased amount of work which the scheme provides for a guaranteed reasonable (though some think not a fully adequate) payment that has led to this improvement. In addition, a large number of physicians find it a relief and comfort that they can now give a fuller attention to many of their poorer patients without the thought that those patients will be afterwards distressed by the presentation of a bill. There is not evidence that the general quality of professional work has in any way deteriorated. No doubt, as in other branches of medical work, there are some who are less skilful and less conscientious than others, but comparing like with like, the best with the best, or the average with the average, it is safe to say that the quality of the service rendered is at least as high among insurance doctors as it is say, in private practice or in hospital out-patient departments.

It is not to be denied that there are certain drawbacks, dangers, or disquieting features which may be found under an insurance scheme for medical benefit. The most commonly mentioned among those which are real, is the multiplicity of rules and regulations which it involves. No doubt there is a tendency to multiply and complicate these unnecessarily, but it should be realized that most of them arise from three extremely valuable and probably unique features embodied in the English system. These are (1) Every registered medical practitioner has the right to be a member of the service unless and until it is proved that, because of misconduct, his continuance therein is detrimental to the service as a whole, (2) the close approximation of the conditions of the service as between doctor and patient to those which obtain in private practice, (3) the considerable share assigned to the profession itself in administration. Because of, not in spite of, the confidence in the profession which these features disclose, provision has to be made for the occasional delinquent. If the state has no right

to choose which physician shall take part in the service machinery has to be established for dealing with anyone who conspicuously fails in his duty. If the state has limited its function to bringing together doctor and patient, leaving them free thereafter to act in accordance with recognized or traditional methods, it must provide means whereby, in case of dispute, each may have a square deal. If the state leaves purely medical matters to be judged by a purely professional body, there must be some authoritative delimitation of the respective spheres and some prescribed means for action. All these statutory requirements, rules, and regulations, need not trouble the physician any more than the ordinary requirements of the penal code trouble the law-abiding citizen. In fact, they do not worry him overmuch. They exist largely for his own protection. There is however a certain type of mind which tends to be distracted by them, and therefore they should be made as simple and few as possible.

Only two other drawbacks or dangers need be considered—the one affecting the attitude of certain members of the profession, the other affecting the mind and conduct of certain insured persons. The one is that the system does to some extent facilitate the procedure of commercially-minded practitioners and the exploitation of unwary members of the profession by ingenious laymen. There is no doubt that insurance practices are more easily and more certainly transferable than ordinary private practices. On the occasion of any such transfer each insured person on a physician's list is afforded the opportunity of choosing another physician but in fact only a very small proportion of them (perhaps 3 to 5 per cent) avail themselves of this at an early date thereafter. This allows of such practices being worked up in suitable areas and then, perhaps at short intervals being bought and sold as commercial propositions. This danger, however cannot be said to be prevalent, and it is one which knowledge and experience should easily combat.

The other drawback is that with a quite small proportion of insured persons, their attitude towards their physician may be changed for the worse. Instead of regarding him as a confidential friend and adviser there are a few who come to demand his services as a business right and may be critical and suspicious lest they should not secure their full due. If there were any widespread effect in this direction it would be enough to condemn the whole system, but in fact the enormous majority of insured patients enter into relations with the physician of their choice in exactly the right spirit, and such an attitude as that described is not common and can be readily dealt with by any wise practitioner.

Other supposed drawbacks or dangers are either unreal, or trivial, or not peculiar to in-

insurance practice but more or less common to many forms of medical work

In conclusion, if, as the result of the British experience, one were to offer any advice to members of the profession or other persons interested in public health elsewhere, one would feel inclined to say with a good deal of emphasis, that, whatever variation there might be in many details of any proposed insurance health service, certain conditions should be regarded as essential for smooth working and success

First the three unusual features of the English scheme mentioned above should be regarded as absolutely fundamental—the right of all doctors to be members of the service, the absence of interference between doctor and patient as such when once this relationship has been brought about, the close and appropriate association of the profession itself with the administration

Secondly, the scheme for provision of medical benefit (i.e., medical advice and treatment) should be separated as completely as possible, both financially and administratively, from any insurance provision for cash payments of any kind

Thirdly, the scheme should, from the beginning, make provision for a full medical service, not merely for general practitioner attention but also for consultant, specialist, and other ancillary services, and, where circumstances allow, for institutional treatment also. Because of historic reasons which govern the provision and maintenance of the institutional care of the sick

in Great Britain, it is found impossible in this country to incorporate hospital provision as an integral part of an insurance scheme, but practicable, however, to secure such provision in direct and intimate association therewith.

Fourthly, the scheme should be administered as simply as possible in topographical areas, and not through a multiplicity of "approved societies." In Great Britain, owing to the vested interests which have already been established, it is recognized that Approved Societies may require to be represented on whatever local committees administer the scheme. Most of the difficulties and complications that have from time to time arisen under the existing English scheme have been due to the fact that these last three conditions have not been fulfilled, and the British Medical Association in the spring of 1930 issued "Proposals for a General Medical Service for the Nation," incorporating the above stated general principles and urging the extension of the sickness insurance law to cover not only the insured employees themselves but also the members of their families, to provide the services of specialists as well as of general practitioners, and to arrange for hospital care, as measures for increasing the provision which the present law furnishes for attending to the health of the people by securing full medical attention for them. Financial stringency has prevented any attempt to establish such provision during the past three years, but the scheme has been very favorably received in general, and it is under discussion by societies and authorities interested in the public health

SNAPPING THUMB IN CHILDHOOD*

Report of Eight Cases

BY HENRY W HUDSON, JR, M D †

THERE are several lesions which may cause flexion deformity of thumb or fingers. Among them are stenosing tendovaginitis, alterations in the phalanges or inter-phalangeal joints, peripheral nerve injury, neoplasm of tendon or tendon sheath, cicatricial and ischemic contractures, and division of opposing tendons. Since effective treatment presupposes recognition of cause and, since in a recent experience with one etiologic factor a correct diagnosis was made in none of eight cases before hospital entry, consideration of that type is pertinent. Furthermore the observation of eight cases in children within a two-year period is a unique experience if one may judge from standard texts and the scant literature. Certain conclusions may be drawn from this experience which are

at variance with the usual statements concerning etiology.

The deformity, with which we are concerned, consists in a flexed position of the distal phalanx of the thumb which is overcome by active extension with difficulty, if at all, and recurs promptly. Passive or active (when possible) extension is accompanied by a palpable, and frequently audible, "snap" or "click" which is often painful. Palpation of the flexor tendon frequently reveals a localized fusiform thickening just proximal to the metacarpo-phalangeal joint.

The diagnosis is made readily without elaborate investigation and a simple surgical procedure is effective in the relief of deformity.

Compere,¹ in a recent report, vividly describes his case, which except for the age of his patient, appears to be identical to those we have seen. His illustrations are very clear and worthy of examination. He classifies his case as one

*From the Surgical Service of the Boston Children's Hospital and the Department of Surgery Harvard Medical School.

†Hudson Henry W. Jr.—Assistant Surgeon Boston Children's Hospital. For record and address of author see "This Week's Issue" page 871.

of tendonitis stenosans and apparently considers flexion deformity due to local tendon enlargement or to local tendon sheath stenosis as fundamentally the same. He separates this condition, however, from that described by de Quervain² as limited to the common tendon sheath of abductor longus and extensor brevis pollicis tendons. The condition described by de Quervain was later shown to involve any of the tendon sheaths about the wrist or hand. Finkelstein³ was able to produce this lesion in rabbits by trauma or by chemical injury and regarded it as the result of aseptic inflammation. He emphasized that the pathologic change is fibrous thickening of the tendon sheath and states that *it is rare for the lesion to occur in the tendon itself*. In one of his cases a localized tendon enlargement was noted. Both Compere and Finkelstein found little American literature concerning this lesion, but both felt it was not uncommon. Compere reviewed forty cases and reported an additional one. Of the forty, *only eight were six years of age or less*, and thirty-three of the thirty-six in which the sex was stated occurred in females¹. Seventeen of the cases resembled those we have seen.

In Keen's⁴ Surgery the author offers the names trigger-finger, and lock-finger, and states that it is rarely congenital and is more often associated with trauma, gout, overuse, and arthritis deformans. He advances circumscribed tendon thickening, new growths, protuberance of joints, and narrowing of tendon sheath as etiologic factors. Da Costa⁵ describes trigger-finger, jerk-finger, lock-finger, snapping-finger, as associated with rheumatism, ganglia, enchondromata, tendon synovitis, tendon sheath thickening, and (quoting Tubby) enlargement of tendon. Babcock⁶ speaks of snap-finger, trigger-finger, spring-finger, as affecting, in order of frequency, the middle and ring fingers, the thumb and index finger. He mentions tendon callus as causative in 90 per cent, and adds contracture of sheath, sesamoid bone or ganglion and alteration in joint surfaces as other causes. Ochsner⁷ states that the condition is rare, that it may affect fingers or thumb, and that it is due to localized tendon thickening or sheath narrowing, or both. Bickham⁸ recognizes the lesion and recommends shaving the tendon or enlarging its sheath or excising the *obstructing nodule*. Ashurst⁹ gives the usual cause as a *fusiform thickening* of one of the flexor tendons. Bunnell¹⁰ describes a *small benign nodule* containing giant cells and believes it the result of slight trauma. Homans¹¹ calls attention to Nélaton's "doigt à ressort" described about 1850 and states that the patients are usually elderly. All agree that the condition is rare in childhood and Finkelstein stresses its relation to manual work. It is usually stated to be much more common in the female.

Cotton¹² reported a case of trigger-finger in

which operation was successful and stated that up to that time (1911) there were about 160 cases on record with operative data in forty. He added "a couple of cases have been reported as congenital in origin". Most, however, were middle-aged persons and the female was more frequently affected than the male. Trauma and occupation were regarded as important factors. Cotton emphasized that the important thing was disproportion between the tendon and its sheath and stated that this was possible either from localized tendon enlargement or localized sheath stenosis.

In contradistinction to the usual statements regarding age, sex and cause, we offer eight cases (two bilateral) seen within two years*, all occurring at age three or earlier, with no distinctive sex incidence, and all with the same etiologic factor—localized tendon enlargement leading to disproportion between the tendon and its sheath. In all these the flexor pollicis longus was affected. In only one instance was there a definite history of trauma and in no instance had the fingers or hand been used in an abnormal fashion. In one case a familial incidence was recorded. Six of the eight cases, including both the bilateral instances, were proved by operation.

CASE REPORTS

No 150401. A. C. a white female of 4 9/12 years reported to the Surgical Out Patient Department June 23 1931. About two years before the child had struck her right thumb "end on" against an opening door. She cried for a short time and then returned to play. About one week later the mother noted that the child held her spoon awkwardly. She was advised to bathe the thumb in hot water for twenty minutes each day. Under this treatment the thumb could be extended easily but within 10-15 minutes it would again become flexed. Later the thumb remained flexed and if passively extended, was painful.

On examination the distal phalanx was held flexed at about 45 degrees. Efforts to extend the phalanx were accompanied by pain and the examiner considered the tendon short. Abduction was limited with the phalanx flexed and there was further limitation of abduction if the phalanx was extended.

Operation was performed July 27. The tendon of the flexor pollicis longus was exposed. A "thickened substance resembling cartilage" was noted in the tendon opposite the metacarpo-phalangeal joint. This was removed, the wound sutured and the thumb splinted in an extended position.

Active motion was instituted 24 hours later. The wound healed well and the child was discharged August 4.

Active extension was possible within 48 hours after operation. The child was followed until September 1933 (22 months). Movements of the thumb were considered normal.

Histologic examination of the excised tissue (S-31 237) showed fibrous and fatty tissue, the fibrous tissue resembling scarred tendon.

*During this period an additional patient was seen in whom the flexor sublimis digitorum (III) was similarly affected.

No 150875 S B a white female of three months reported to the Surgical Out Patient Department July 6, 1931 because of a deformity of the thumb noted one week earlier. The terminal phalanx of the right thumb was held flexed at about 45 degrees but could be passively extended. The tendon of the flexor pollicis longus was considered "tight". Passive extension was recommended and the infant was followed for three weeks during which there was improvement. An attempt to follow this patient was unsuccessful.

No 151701 F I a white male of six years reported to the Surgical Out Patient Department July 30, 1931. From infancy (one year) his mother had noted his inability to extend the distal phalanx of either thumb. There had been no pain and he had suffered no inconvenience until he entered school when it was difficult to teach him to hold a pencil. A similar flexion deformity was noted and attempts to extend the phalanx were unsuccessful. When forced toward extension, the thumb dislocated at the metacarpophalangeal joint. Again, the examiner considered the tendon to be short.

On August 8 the tendon was exposed. Opposite the metacarpophalangeal joint the tendon was thickened and could not be moved freely. A segment of the sheath was removed with relief. Similar operations were done on the two tendons. The tendon thickening was more marked on the right side.

Active motion was allowed within 24 hours. The wounds healed well and the boy was discharged in ten days with full motion in the left thumb but with slight loss of full extension on the right.

He was followed until October 26 (two months). At that time the function of the left thumb was normal. The right thumb was extended but there was loss of flexion.

No 149745 H D a white female of 1 5/12 years was admitted to the surgical wards November 10, 1931 for repair of an umbilical hernia. An incidental observation was a deformity of the left thumb whose distal phalanx was held flexed at 45 degrees and could not be extended actively or passively. No operation was performed on the thumb but exercises were prescribed. On September 15, 1933 (22 months later) there was no improvement. Operation has not been done because of a social problem.

The mother, maternal grandfather, and maternal great grandmother were all said to have "curved" little fingers which could not be "straightened"

No 153797 R McM a white male of 4 6/12 years was admitted to the surgical wards January 22, 1932. At 1 3/12 years, without history of injury, a flexion deformity of the right thumb was noted. It persisted, without change, despite forceful passive extension and splinting carried out on several occasions a year before he was brought to the hospital.

The typical deformity was present, active extension was impossible, and one examiner considered the tendon prominent.

January 22, under ether anesthesia the distal phalanx was extended. Extension was accompanied by an audible and palpable "snap". A local tendon enlargement was palpable. A splint was applied to maintain extension. Within a few hours the child had loosened the splint and his deformity had recurred. The following morning without anesthesia, the phalanx was again extended, again with an audible and palpable "snap" and transient pain. No splint was applied. In two hours there was recurrence. No swelling followed either manipulation.

January 26 operation was performed. A globose enlargement of the tendon of the flexor pollicis

longus was demonstrated. It caused disproportion between tendon and tendon sheath. A segment of the sheath was excised.

Active motion was allowed in 24 hours. There was relief of deformity. The child was followed for 21 months. Motion was normal.

No 107404 O A. a white female of 6 4/12 years entered the surgical wards September 8, 1932. When she was about two years old, her mother noted that the left thumb was not straight. This persisted. At age three a similar appearance was noted on the right side. From time to time the child would passively extend these distal phalanges, but flexion of 45 degrees promptly returned. There was no pain. There was no history of trauma or infection.

The usual deformity was present on either side. A firm tendon enlargement was palpable opposite either metacarpophalangeal joint.

On September 9 both tendons were exposed and a fusiform enlargement noted "just distal to the point where the tendon sheath began". The sheaths were incised which allowed the enlargement "to slide freely back and forth" and "permitted complete extension". Splints were applied for 24 hours. Thereafter active motion was allowed. Within three days normal motion was present.

On September 23 and 30 normal motion was present. On April 20, 1933 she reported with a recurrence on the right side. The movements of the left thumb were normal. The recurrence was said to have been noted six weeks after operation. It resembled the original deformity except that local tendon thickening was not palpable.

On August 17 the tendon of the right flexor pollicis longus was again exposed. The local enlargement present a year before was no longer present. With the distal phalanx completely extended the tendon was free to move in its sheath.

The child was discharged, unimproved, August 26. On September 18 she reported with a wound infection which had developed during chicken pox and had been discharging for several weeks. A silk suture was removed. On September 21 the wound was healed. The left thumb was normal. There was flexion deformity of the right thumb.

No 166166 D B a white male of 2 1/2 years was admitted to the Orthopedic Service on January 4, 1933. Two months earlier a flexion deformity of the right thumb had been noted. There was no history of preceding injury or illness. No abnormal use of the thumb had been noted. The child was a thumb sucker but this was confined to the left and not to the affected thumb. The deformity remained unchanged from the time it was first noted until admission except for slight temporary improvement under massage.

Local examination revealed a 45 degree permanent flexion deformity of the right thumb. Flexion was not limited but extension was possible to 145 degrees only. Passive extension to nearly 180 degrees was possible but the 45 degrees of flexion promptly recurred.

On January 6 the flexor tendon was exposed and its sheath incised. "In the deep portion of the sheath at the metacarpophalangeal joint a small fibroma" measuring about 0.5 cm in diameter was found. It was adherent to the tendon. It was removed and immediately full extension was possible.

The child was followed until September 30 (nine months). The flexion deformity was entirely corrected but there was loss of active flexion of the distal phalanx. Other motions were normal.

The histologic report (S 333) follows: "One section shows heavy bands of dense connective tissue in which few nuclei are found. At one edge the

fibrous tissue merges with an area of hyalin cartilage. In the transition from the connective tissue to the cartilage there is a small amount of fibro-

The lower photograph shows the flexion deformity of the distal phalanx. The upper two show the active motion possible two days after operation.

cartilage noted. At some distance from the area of cartilage just described there is a small amount of fibrocartilage living in connective tissue and merging gradually and almost imperceptibly with

the fibrous tissue. The picture is consistent with a congenital anomaly of development and can be best described by the term cartilaginous transformation of fibrous tissue."

No 172273 R B a white female of 1 10/12 years was admitted to the surgical wards on June 27, 1933. For two months, flexion deformity of the left thumb had been noted. There was no history of trauma. At times active extension had been possible but more frequently the distal phalanx was flexed at about 45 degrees and could not be extended. A palpable localized enlargement of the flexor pollicis longus was present opposite the metacarpo-phalangeal joint.

On June 28 the tendon was exposed through a one inch incision, the sheath was incised and an oval localized tendon enlargement demonstrated. The sheath was resected for about 1/4 inch.

There was immediate relief of deformity and motion was normal.

The child was followed until September 16 (3 months). Motion was normal. The tendon thickening palpable before operation was no longer palpable.

This experience suggests that those instances of snapping thumb or finger due to localized tendon enlargement represent instances of developmental aberration in the tendon or its sheath, or both, possibly with hereditary transmission, and that age, trauma, and occupation are contributory and not causative factors.

STRANGULATED INGUINAL HERNIA, WITH UNUSUAL COMPLICATIONS, IN AN INFANT OF FIVE WEEKS

Report of A Case

BY J. L. GOLDEN, M.D.,* AND H. H. HAMILTON, M.D.*

WH. a well developed and well nourished male infant five weeks of age, full term normal delivery breast fed present weight of 8 lbs 2 ozs., with no previous history of illness, was brought to the hospital by his mother, with the following history:

Friday morning two days before entry the patient was irritable crying hard and often. The irritability continued throughout the day, but there was no vomiting and the bowel movements were nor-

mal. The following day vomiting began and occurred a few minutes after each feeding. It was projectile in nature. Sunday morning the day of entry the diaper was noted stained with pink fluid. There had been no bowel movements since noon the day before. Vomiting persisted and was now brownish in color. The odor was not noted. For the first time, 48 hours after onset of symptoms, a mass the size of a walnut, was noticed by the mother in the right groin.

On admission a slightly dehydrated, drowsy infant was presented. Head, chest, and extremities showed no abnormalities. Extending from the mid-

*Golden, J. L.—Assistant Surgeon, Malden Hospital, Malden, Massachusetts. Hamilton, H. H.—Resident Surgeon, Malden Hospital, Malden, Massachusetts. For records and addresses of authors see this

on the right was an ovoid mass about two inches long and one inch in diameter. The skin was red dened over the lower half of the mass, and the redness extended down over the entire right half of the scrotum. It did not transilluminate, was indurated, and showed a slight amount of pitting edema. When it was touched, the child cried out. Attempts at reduction were considered inadvisable. Rectal temperature on admission was 99.5°, pulse 140, WBC 15,000. The patient cried out sharply and writhed for a few seconds every two or three minutes, remained quiet between the attacks, and often dozed off to sleep.

Preparation for operation was made at once. Shortly after entry a small amount of greenish material was vomited. A soap suds enema returned with good results. The preoperative diagnosis was strangulated right inguinal hernia.

OPERATION

Under ether anesthesia, the field was prepared with a mercurochrome acetone-alcohol solution, and a two and one half inch incision was made one-half inch above and parallel to Poupart's ligament. The tissue layers were identified and divided down to the inguinal canal, where a hernial sac about two inches long and one inch in diameter was found extending from the internal inguinal ring into the scrotum. On opening the sac, a small amount of sero-sanguineous fluid escaped. The right testicle, with the spermatic cord, was found included in the sac, and these structures were gangrenous up to a point about one-half inch from the internal ring. The testicle had the appearance of a small, ripe olive. Superior to the testicle was about two inches of small bowel, the ileocecal valve, and a small portion of the cecum in the sac, forming a loop extending down to the testicle. On separating the loop of bowel, the appendix was exposed lying free in the hernial sac, markedly injected, porky and edematous. The appendix and its mesentery were ligated with atraumatic catgut, removed and the stump carbolyzed. It was found impossible to reduce the herniated bowel which was moderately injected and edematous, but evidently in a viable state, until the internal abdominal ring was enlarged superiorly. Reduction was then perfected, and the neck of the sac closed by mattress atraumatic sutures. As circulation in the testicle and spermatic cord had shown no tendency to return, these organs were next removed. Anatomical repair was then done, the external oblique fascia being overlapped and plied. Dermal suture was used on the skin. A small rubber wick was inserted into the scrotum

through the lower end of the wound and left in place for 24 hours. A collodion dressing was applied.

PROGRESS

The temperature rose to 103.5° on the day following operation, and there was a watery diarrhea of about twelve bowel movements during the first 24 hours. Small clyses and paregoric were administered. On the fifth day, the temperature was normal and remained so. The sutures were removed on the seventh day, and the patient was discharged the sixteenth day postoperatively with the wound entirely healed, and a weight gain during his stay in the hospital of 14 ounces.

PATHOLOGICAL REPORT

"On section, the testicular tissue is found to be extremely hemorrhagic. The normal anatomy cannot be made out in the gross. The appendix measures 4.5 cm. in length and 6 mm. in diameter at its widest portion. There is moderate injection of the external vessels. On section, the wall is found to be of normal thickness, the lumen is patent and contains homogenous material.

"Sections microscopically through the testicular tissue show a marked acute inflammatory change, characterized by hemorrhage and polymorphonuclear infiltration. The tissue contains numerous, large, dilated blood vessels filled with red cells. The spermatic cord shows a similar microscopic picture. The appendix shows evidence of an acute inflammatory process. The vessels of the serosa are markedly injected with foci of perivascular infiltration. It is accompanied by considerable edema. There is no evidence of any malignant change in the tissue submitted for examination.

"Pathological diagnosis: Acute inflammation of appendix. Acute inflammation of testicle, probably due to torsion." (The possibility of torsion was considered at the time of operation, but there was no evidence of such a condition.)

We have reviewed the literature during the past five years, both American and foreign, and find no cases of this type reported. There have been, however, five cases of appendicitis with strangulated hernia, which have been reported in the foreign literature. In none of these cases has there been involvement of the testicle, and no one of them has been an infant. We are reporting this case because of the patient's age and the extraordinary complications encountered.

THE MECHANISM OF A SPRAINED ANKLE

BY ALEXANDER P. AITKEN, M.D.*

ALTHOUGH there is nothing more common than a sprained ankle, little can be found in the textbooks to explain what structures are involved and what actually takes place when an ankle is sprained. The structures which are said to be most commonly involved are the deltoid ligament, the anterior and lateral bundles of the talo-fibular ligament and the calcaneo-fibular ligament. Our experience leads us to be-

lieve that it is only in the exceptional case that these structures are involved. We find, as others have already pointed out, that in the great majority of cases the point of maximum tenderness lies just medial to the external malleolus. This point corresponds to the distal tibio-fibular joint and lies directly over the anterior ligament of the external malleolus (anterior tibio-fibular ligament). We believe that this is the structure most commonly injured in sprains of the ankle. (Figs 1 & 2)

The manner in which this injury occurs is as

*Aitken, Alexander P.—Assistant in Surgery, Boston City Hospital. For record and address of author see "This Week's Issue," page 871.

follows. The ankle joint consists of a relatively square mortise made up by the tibia and fibula, and a relatively square tenon, the as-

FIGURE 1

FIGURE 2

FIGURE 3

A ANTERIOR TIBIO-FIBULAR LIGAMENT
B FIBULA
C TIBIA

tragalus. When the foot is held at right angles, the wider anterior portion of the body of the astragalus fills the cavity of the mortise. With the foot in this position any sudden twisting of

the foot, especially inversion, will have a tendency to twist the astragalus in the snugly fitting mortise prying it apart (Fig 3). When one takes into consideration that the entire body weight is being exerted on the ankle at the time of the injury, one can appreciate the tremendous leverage thus brought to bear upon the mortise.

Now the mortise is not a complete bony structure. It has one decidedly weak point, namely at the tibio-fibular joint, and it is at this point that the mortise tends to give way. Tension is thus placed on those ligaments which bind the fibula to the tibia, the anterior and posterior ligaments of the external malleolus (anterior and posterior tibio-fibular ligaments). As the anterior portion of the mortise is in much closer contact with the wider anterior portion of the body of the astragalus, most of the tension is thus brought to bear on the anterior portion of the tibio-fibular joint. As a result of this tension we get tearing or stretching of the anterior tibio-fibular ligament which accounts for the pain and tenderness just medial to the external malleolus.

We have described this lesion as occurring with the foot being forced into inversion. However, it is perfectly possible for the same picture to appear, should the foot be forcibly everted. However a fracture of the internal malleolus is more common in this type of injury.

The above is of course not the complete picture seen in most sprains. There may be a general stretching of the other ligaments and tendons, which in the latter may amount to a tenosynovitis. There also occurs injury to the overlying soft parts with subcutaneous hemorrhage.

In our series of cases we have found the above picture in well over 80 per cent of the cases.

A COMFORTABLE BREAST SWATHE

BY ERNEST M. DALAND, M.D.*

SEVERAL years ago the late Dr. Frank Richardson suggested to the writer that the breast dressing described below be substituted for the double binder then in use. The inner swathe or binder had been used to hold the breast dressing in place postoperatively and the second binder had been passed around the arm as well as the chest. Patients had been complaining bitterly about the double binder and had often pleaded to have it removed or loosened.

The chest swathe is applied as usual but care is taken that the swathe used is not too wide and that it does not arch upward in the front or back above a line drawn between the apices of the axillae. This swathe is made of Canton flannel. A second swathe of the same type is then folded lengthwise three times, making its width one third that of the first. It is fastened to

the first swathe posteriorly by two pins, brought over the shoulder and pinned to the first swathe in front. This makes a comfortable shoulder

strap and serves to hold that part of the dressing over the pectoral region in place. The folded swathe is then brought down to the center of the chest swathe, anchored with one or

Daland, Ernest M.—Chief of Surgical Out Patient Department, Massachusetts General Hospital. For record and address of author see "This Week's Issue," page 871.

two pins, turned on itself, carried around the arm, back to itself where it is anchored with another pin

Aside from holding the dressing in place, the purpose of any postoperative breast dressing is to make the patient comfortable. She is uncomfortable if she abducts the arm, but there is no reason why she should not move the forearm, for it does not give pain. Abduction also disturbs the healing of the skin flaps by making a dead space beneath them.

The dressing described acts as a sling for the upper arm and the arm is more comfortable than if a pillow is used to keep it from drop-

ping backward. It allows a slight amount of movement of the arm across the chest and it allows full motion of the forearm. It is used during the first four or five days after operation. When it is removed the patient is ready to start active but limited use of the arm. No passive manipulation is ever used. The patient is never urged to use the arm, nor is it suggested that she is in danger of not regaining full motion. However, the average patient is able to comb her hair by the time she is discharged from the hospital, whether she has had a simple or a radical operation.

THE HEEL SHIFTING OPERATION FOR FLAT FEET,— AND OTHERS

BY FREDERIC JAY COTTON, M D ‡

LONG, long ago an ingenious German named Gleich devised an operation

Years afterward, I chanced on his report and promptly adopted the method for a variety of purposes

The essence of the thing is a shifting of the back end of the os calcis to readjust the relations of the weight-bearing line of the leg and the much discussed "triangle of support" of the plantar foot surface*

About the same time it was my privilege to work with Dr. Robert Lovett on a bit of investigation and presently we evolved some basic facts and principles† that rather supplanted a lot of the previous work, mainly German

This changed a lot of ideas as to mechanical physiology of the foot, and cleared our heads very much

Nevertheless the old idea of sheer static weight bearing was sound, and the idea of importance of the relation of the weight-bearing line of the leg to the weight-sustaining triangle of the sole, held true

Also the ability to shift the rear point of this triangle, the heel, surgically, remained most important

Oddly enough Gleich's idea has never been largely utilized—to my knowledge

His operation rested on the possibility of shifting the rear end of the os calcis inward, after division of the "neck" of the bone with a Gigli wire saw

The saw seems unnecessary and less desirable than a clean cut with a thin osteotome which leaves surfaces less burned over and irregular

*The triangle is formed by the distal heads of the first and fifth metatarsals and the plantar bearing point of the os calcis. The weight bearing line is down the tibia to the middle of the astragalo tibial joint

†Lovett R. W. and Cotton F. J. Some pathological practical points in the structure of the foot. Tr. Am. Orthop. A. 11 293 1898

‡Cotton Frederic Jay—For record and address of author see This Week's Issue page 371

enough to make entanglement or any desired impaction easy and effective

The approach may be anywhere (easily managed from the outer side) so as to cut down and forward

With the heel once free one may carry it inward or outward, downward, or down and forward

MOBILIZATION OF HEEL

Upper figure Shows the cut across the neck of the os calcis. The dotted line shows the heel shifted downward and somewhat forward.

Lower figure Shows the ankle from behind. The heavy lines show the cuts across the bone varying in direction (in this plane) according to the purpose of the operation.

The heel may be displaced along the line of these cuts to give the various corrections indicated by the various dotted lines.

According to what is desired the slant of the cut may be varied in two planes as the illustrations show. This makes any sort of correction easy, with maintenance of adequate bone contact.

One need not hesitate to do radical shifting of the heel, or to secure the position once gained by producing light impaction with a hammer on the thick weight-bearing pad of the heel.

Maintenance of position is secured with a plaster of Paris boot

Union, as always where the os calcis is concerned, is amazingly prompt.

Weight-bearing may be begun carefully, as early as a month after operation

Devised for palliation of the extreme flat feet so common in European peasants, the operation first proved itself here in the correction of valgus deformity in old consolidated os calcis fractures then in certain selected cases of flat foot and also in varied valgus and varus deformities,

notably in the correction of the rather common residual twist inward of the heel seen in club feet otherwise adequately corrected, whether congenital or of paralytic origin

The operation is very simple

Its adaptation to the case in hand demands, and rewards, a certain mechanical deftness

MEDICINAL WHISKY RULING ISSUED BY FEDERAL DRUG OFFICIALS

The Food and Drug Administration recently issued a statement intended to clarify the specific requirements of the Federal Food and Drugs Act as they apply to medicinal whisky. The announcement supplements but does not in any way conflict with the labeling regulations covering beverage whisky recently issued by the Federal Alcohol Control Administration. It shows that whisky sold for drug purposes is subject to requirements which do not apply to an article intended exclusively for beverage use.

The Food and Drug Administration emphasizes that the requirements it enforces in regard to medicinal whisky are not administrative rulings but are set forth in the Food and Drugs Act which requires that drugs listed in United States Pharmacopoeia shall conform to the definition in that authority. The definition for whisky in the U S Pharmacopoeia is more rigid than the definition for 'straight whisky' which the FACA issued February 6 1934 in that Pharmacopoeia whisky must be aged four years in charred wood containers and its alcoholic content must be not less than 47 per cent and not more than 53 per cent by volume of absolute alcohol. Medicinal whisky which does not conform to the pharmacopoeial standard must be labeled to differentiate it clearly from the official product. The Food and Drug Administration statement includes illustrations of labels which will be regarded as legal on such products.

The statement issued recently applies to medicinal whisky sold in the District of Columbia and to whisky for medicinal use shipped in interstate commerce throughout the United States.

The text of the ruling follows:

A drug sold within the jurisdiction of the Federal Food and Drugs Act as "Whisky" "Spiritus Frumenti" or "Sp Frum" must comply exactly with the definition for "Whisky" in the U S Pharmacopoeia and otherwise satisfy the provisions of that authority for "Whisky". It must be labeled with a statement of the quantity of alcohol in terms of the percentage by volume of absolute alcohol.

A drug varying from the Pharmacopoeial specifications for "Whisky" in strength, quality or purity (but not in the identity of its constituents or of the materials from which it is made) may be sold as

"Whisky not U.S.P." if the label carries a declaration of its own standard of strength, quality and purity. It may be (1) an article conforming to the definition in the U S Pharmacopoeia except with respect to time of aging percentage of alcohol and content of acids and esters, or (2) a mixture of (1) with grain alcohol or grain alcohol and water, or (3) a mixture of U.S.P. whisky with grain alcohol and water. It may not contain alcohol from non grain sources nor may it contain any substance not present in U.S.P. whisky. Such a drug may be labeled as in the following three examples assuming it to be of the indicated composition in each case:

Whisky
Not U.S.P.
Aged — years
Alcohol by Volume —%

Whisky
Not U.S.P.
—% straight whisky aged — years —%
neutral spirits from grain
Total Alcohol by Volume —%

Whisky
Not U.S.P.
—% U.S.P. Whisky —% neutral spirits
from grain
Total Alcohol by Volume —%

Diluted alcohol (from whatever source) with or without artificial flavor and color is not entitled to the name "Whisky" however qualified if sold as a drug but may be sold as a drug under any other name which is not false or misleading in any particular.

A pharmacist in the District of Columbia filling a prescription for "Whisky" "Spiritus Frumenti" or "Sp Frum" must fill it only with whisky conforming to the requirements of the U S Pharmacopoeia. If a physician prescribes "Whisky not U.S.P." and specifies the standard of strength, quality or purity desired, the prescription must be filled with a product conforming to such specifications.

This announcement shall not be construed as modifying or changing the regulations of the Federal Alcohol Control Administration relative to the labeling of distilled spirits but shall be considered as an addition thereto—*Bulletin, U S Department of Agriculture*

CASE RECORDS of the MASSACHUSETTS GENERAL HOSPITAL

ANTE MORTEM AND POST MORTEM RECORDS AS USED
IN WEEKLY CLINICAL PATHOLOGIC EXERCISES

EDITED BY RICHARD C. CABOT, M.D.
F. M. PAINTER, A.B., ASSISTANT EDITOR

CASE 20161

PRESENTATION OF CASE

An American engineer thirty-three years old entered complaining of vomiting, fainting, and bloody and tarry stools.

For the past ten years the patient had had occasional vague attacks of indigestion consisting principally of gas and a feeling of fullness in his abdomen. Relief was always obtained by the taking of soda or milk of magnesia and lying down for a few minutes. There was no real abdominal pain. These symptoms were not all related to meals and were not relieved by food. During the three months prior to entry this vague abdominal discomfort became more noticeable. Seventeen days before admission he noticed a dull aching pain high up in the epigastrium and in the left hypochondrium which after lasting for fifteen or twenty minutes seemed to "work through to his back", producing a dull pain at about the first lumbar segment in the midline. This pain came on several hours after meals, did not awaken him at night, and was not relieved by food or soda. Two weeks before admission he passed a moderate sized tarry stool. This was not associated with weakness or faintness. One week before admission he became nauseated one evening and vomited about a half a glassful of black material. He felt considerably relieved, but was somewhat weak and dizzy. He felt well the next morning. Four days before admission he had some epigastric pain and passed two tarry stools. On the night before admission he passed another tarry stool, had profuse sweating, became very weak and dizzy, and later vomited about a pint of black material, following which he fainted for a few minutes. He was brought to the Emergency Ward in an ambulance and shortly after arrival vomited half a kidney basinful of brick red blood.

His family and past histories are negative.

Physical examination showed a well nourished man lying on the shock table sweating profusely. The skin and mucous membranes were pale. The heart was not enlarged. The sounds were distant. No murmurs were heard. The blood pressure was 70/55. The lungs were clear. The abdomen was scaphoid. There was a lower right

rectus scar. There was slight tenderness in the epigastrium upon pressure. Rectal examination was not done. The knee jerks and ankle jerks were not obtained. Babinski was negative.

The temperature was 100°, the pulse 140. The respirations were 16.

The examination of the urine was negative. The blood showed a red cell count of 2,870,000, a hemoglobin of 50 per cent. The white cell count was 15,800, with 65 per cent polymorphonuclears. The stools showed a four plus guaiac.

The day following admission he was given a blood transfusion of 300 cubic centimeters and 1000 cubic centimeters of ten per cent glucose. The blood pressure remained about 120 systolic throughout that night. The following morning he vomited 500 cubic centimeters of bright red blood, following which his blood pressure dropped to 50 but gradually went back to 85. He was given 200 cubic centimeters of citrated blood and the same amount of ten per cent glucose. A surgical consultant advised frequent transfusions until the blood pressure was well above 100. He also advised that surgery should not be urged until the patient had picked up, which would probably be in about two months. Intravenous glucose and transfusions were continued. On the sixth day a note was made that it was three days since the last hemorrhage and that everything was going well. The pulse had gradually fallen to 80 and the blood pressure had averaged between 110 and 125 systolic. The patient had taken some cracked ice at half hour intervals. The next day he was put on milk and cream, one ounce every two hours. On the sixth day he was given a second stage diet with powders. That evening he passed a large hard black stool. The following day, after another hemorrhage, he was transferred to the Surgical Service and was operated upon.

The day following the operation the temperature was 104°, the pulse 140. He had signs of a slight collapse at the right base and was put in an oxygen tent. X-ray of the chest showed mottled areas of consolidation throughout, both lung fields. Physical examination showed coarse râles throughout the chest, with a large patch of bronchial breathing at the right base. He was transfused several times. He continued to cough up about six or seven ounces of foul sputum daily. The wound drained profusely. Postural drainage and neoarsphenamin were continued, but he rapidly went downhill. His temperature ranged between 101.5° and 103°. He died twenty-four days after operation.

X-RAY INTERPRETATION

DR. GEORGE W. HOLMES. We did not have a chance to examine his gastro intestinal tract. We have the films of the chest here. This is the first film, taken the day his temperature went up or the day after. It shows definite lesions in both lungs, large soft mottled areas

which to me do not suggest massive collapse I suppose it is possible that they were due to alveolar collapse, but it would be very unusual to have even that type scattered through both lungs. The appearance is much more suggestive of multiple infarcts or of bronchopneumonia. As yet I do not know how to distinguish between early infarct and bronchopneumonia.

In this film taken nine days later, the process in his lungs has apparently cleared up with the exception of an area on the right side near the angle of the scapula. There is a considerable difference in the exposure time of these two films and soft small areas might easily be blotted out, although I hardly think that is the case. The diaphragm is in the usual position in both sets of films, and the heart is not displaced.

In a film taken a few days later, on the twenty-fourth day,—a softer film, which would certainly show anything that the other showed—the left lung is practically free from any disease as far as we are able to demonstrate disease by x-ray. On the right side the patch that was previously noted is still present somewhat larger and more diffuse, and looks like a pneumonia, still it could be an infarct. These were all portable films.

In the film taken just before death we can see that the process is very extensive in both lungs, and of the same general character as before. The film taken of the abdomen shows an unusual amount of density on the right side, nothing else.

From the point of view of x-ray the problem here is to distinguish between multiple infarcts of the lung and pneumonia. We were unable to demonstrate an abscess cavity at any time. If it was a pneumonia it was probably a bronchopneumonia that cleared up, then something else happened. I can make no definite diagnosis.

FURTHER HISTORY

The operation was performed under ether and lasted an hour and twenty minutes. It consisted of ligation of the vessels of the lesser curvature, cauterization of the ulcer, and posterior gastro-enterostomy.

DIFFERENTIAL DIAGNOSIS

DR. DONALD S. KING. I do not think it necessary for me to discuss the part of the story which relates to the gastric ulcer. The operation proved that the patient had an ulcer and I shall leave to the surgeons the discussion as to the optimum time of operation on these cases with profuse hemorrhage. From the medical standpoint the principal problem is that of the pulmonary complication, and we have only a few lines at the end of the case record to throw light on this condition.

In the first place the operation was performed under intratracheal anesthesia. This adds interest to the case, because the surgeons and

anesthetists at the hospital have grown to feel that cases which have received intratracheal anesthesia have very rarely developed pulmonary complications.

Of particular interest in this case is the occurrence of foul sputum. The case record as given to me for study did not mention the occurrence of foul sputum. This fact was left out, I suppose, intentionally. I am interested in knowing if this patient had mouth sepsis, because there is reason to believe that in many cases with pyorrhea and extensive dental caries there is inhalation of this septic material and a resultant spirochetal pneumonia. Such pneumonia has been rare in this hospital, but Dr. Churchill has spoken of cases that he observed at the City Hospital. Personally, I have not observed a case of pure spirochetal pneumonia in this hospital. Was anything said in this patient's hospital record about the condition of his mouth?

DR. M. J. BACHULUS. Examination of his mouth at entry showed dirty carious teeth and retracted reddened gums.

DR. KING. He did have, then, mouth lesions from which material containing spirochetes could be inhaled, but if he did inhale this septic material from the mouth in spite of an intratracheal anesthesia this is an interesting phenomenon.

From a statistical standpoint, the fact that he was given ether anesthesia does not give me any great concern, especially if the ether is given carefully by the intratracheal method.

The day following operation the temperature was 101°, the pulse 140, findings which are not typical of an ordinary collapse, especially since the record notes signs of only slight collapse at the right base. With this temperature we would ordinarily expect a very severe bronchopneumonia of a character which often results fatally.

He was put in an oxygen tent, so that he must have been in a rather serious condition. He would certainly not have been put in the tent for only a slight collapse.

The x-ray, as Dr. Holmes has demonstrated, shows mottled dullness throughout both lung fields. Certainly this is not the picture of collapse.

He had coarse râles throughout both chests and a large patch of bronchial breathing at the right base. These signs might be due to pneumonia or collapse with the bronchus open, but from the general x-ray picture one would say pneumonia.

He coughed up six or seven ounces of frothy sputum daily. This is not characteristic of collapse pneumonia, or abscess. The fact that he had foul sputum later, however, makes one think definitely of abscess or spirochetal pneumonia.

I have no doubt that Dr. Allen would like to overlook the fact that the surgical wound drained

profusely and to put the responsibility for the patient's death on the medical condition I am accustomed to that, because I find that at autopsy the surgeon will always attach more importance to a small area of pneumonia than to a large area of peritonitis. Nevertheless in this case I must grant there was enough in the lungs to account for the fatal termination. The patient died twenty-four days after the operation, apparently after a long and stormy course. This is certainly not the story of collapse. It may be bronchopneumonia, but in view of the foul sputum it is not the ordinary bronchopneumonia. I assume that spirochetes were found in the sputum, otherwise he would not have been given neo arsphenamin.

DR TRACY B MALLORY None were found.

DR KING It is interesting if an abscess did really develop in spite of early neo arsphenamin treatment. Dr Lord and I have been going over the lung abscess cases which have been treated by neo-arsphenamin, and with the data now at hand we have not been able to find any evidence that such treatment has been of definite value. In this case, at any rate, it did not seem to help.

I had not seen the x-ray films until the present time, but before I had seen them I believed that we were dealing with either a lung condition brought about by septic emboli or a spirochetal pneumonia due to inhalation of septic material from the mouth. We have had, so far as my experience is concerned, very few post-operative pulmonary complications of this sort which were proved at autopsy to be due to embolic processes. I remember well one patient who died two days after operation who had an x-ray film similar to this one, though with less mottling. He died with all the symptoms of pneumonia and none of the characteristic symptoms of pulmonary emboli or infarct. The autopsy showed multiple septic emboli apparently arising from a phlebitis in the leg, so that if there were a definite source for septic emboli in this case, the whole picture might be explained on this basis. With the facts at hand, however, it seems to me more reasonable to call this a spirochetal pneumonia rather than an embolic pneumonia or a true lung abscess. Certainly no large lung abscess has been demonstrated, and the process was so diffuse throughout the lung that my diagnosis would be a spirochetal bronchopneumonia with possible abscess formation.

CLINICAL DISCUSSION

DR ARTHUR W ALLEN This patient was thirty-three years of age. He had had indigestion for a period of several years and acute stomach symptoms for nearly three weeks before he came in here. The commonest source of

profuse hemorrhage from the upper gastrointestinal tract in a patient of this age is duodenal ulcer. It outweighs all the other causes tremendously.

We have had in this hospital one hundred and thirty-nine cases of massive hemorrhage from duodenal ulcer in the past twenty years. Twenty of these have died of hemorrhage. I am sorry to say that I do not know how many cases of fatal hemorrhage we have had from other causes, but I believe the number will prove to be very much smaller than from duodenal ulcer hemorrhage. We have had one death that we know about from a polyp of the stomach. We have had one death from hemorrhage in a profuse gastritis. Dr Means called our attention at one of these meetings not long ago to one death from hemorrhage in carcinoma of the stomach. We have had one fatal hemorrhage from a gastrojejunal ulcer. Gastrojejunal ulcers are apt to bleed, but not in such amounts as this one did.

We assumed that this man had a posterior wall duodenal ulcer with an erosion of a vessel overlying the pancreas. We have found that in the deaths that occurred under fifty years of age the mortality was 44 per cent, over fifty years of age the mortality was 33 1/3 per cent. I do not believe that patients of this type can be successfully operated on in a depleted state with a mortality as low as 44 per cent. I think that they probably can be operated upon with a mortality lower than 33 1/3 per cent. So given a patient under fifty with a posterior wall duodenal ulcer with massive hemorrhage, I think we should give him the benefit of the doubt and allow him to recover under a medical régime. If he were in reasonably good condition and fifty, or a little over, or nearly fifty, I think we should be inclined to operate on him as soon as he recovered from shock, providing the medical men would permit it.

This man had an unusual lesion to produce a massive hemorrhage. He had a large ulcer of the upper posterior wall of the stomach which had eroded the main vessel along the lesser curvature. In retrospect possibly we might have suspected that the lesion was not a duodenal ulcer, because the course was not like that of a duodenal ulcer. At his age he should have stopped bleeding and not have bled again so profusely, so quickly. However, we waited a week or a little longer, and finally after this last profuse hemorrhage we felt that he was certainly doomed to bleed to death and that we had no right to wait longer, so as a last resort we did a big operation on a man who was in an extremely depleted condition.

We wanted to protect the patient as best we could and gave intratracheal anesthesia, a total of two ounces of ether during the operation. The other chart is here. It is interesting that he had no fall in blood pressure at all during the operation, which went along very smoothly. On

opening the abdomen we found an enormously dilated stomach. It was perfectly obvious that the duodenal region was free, there being no induration in that region such as we always get when we are dealing with a duodenal ulcer. The stomach revealed induration not far from the cardia in a very inaccessible area. It could not be approached with any other method than by opening the anterior wall of the stomach. This was done. A clot which was in reality a cast of this huge stomach—this cast probably weighed five pounds—was removed first and then the ulcer was exposed. It was about 3 centimeters in diameter, and on its anterior border was a thrombosed vessel. As soon as this was manipulated the thrombus came away with a tremendous gush of blood from the vessel. The vessel was two or three millimeters in diameter, so that having it exposed it was possible to ligate the vessel on the outside and stop the bleeding. It was not possible to cauterize the base of the ulcer successfully, although that was attempted. Having stopped the hemorrhage, the anterior wall of the stomach was closed and a posterior gastro-enterostomy done, because for some reason or other his pylorus though patent did not function properly. It is a well known fact that often in gastric ulcer the physiology of the pylorus is abnormal.

The wound became septic and the discharge had a very foul odor. As one came into this man's room one remembered cases of abscess of the lung one had seen. The odor was terrific. The pus in the abdominal wall smelt the same as that in the sputum and I believe proved bacteriologically to be the same. The abdominal wall sepsis responded to conservative measures and did not, we think, play any marked rôle in this man's exitus.

DR FREDERICK T LORD With respect to the diagnosis of the postoperative disturbance, the odor of the breath suggested pulmonary abscess. There was a different odor from the abdominal wound as compared with that from the breath. As far as the pulmonary condition is concerned the clinical aspects were consistent with a pulmonary abscess.

Dr King has spoken of our experience in reviewing cases of pulmonary abscess. This was an important experience with respect to the ineffectiveness of neoarsphenamin in an early treated patient. In addition to what Dr King has said, on two occasions we have noted the extension of a pulmonary abscess under treatment with neoarsphenamin. While we are not able to settle the question of the merits of neoarsphenamin, our experience here does not suggest that it has merit.

With respect to the problem of surgical interference in patients with bleeding peptic ulcer, resulting shock and profound anemia, this is my second recent experience. The first patient, discussed last July (Case 19302, *N E J of Med* Vol 209, No 4, July, 1933) died in consequence

of a postoperative subdiaphragmatic abscess and this patient succumbed to postoperative complications. Of the 138 cases in Allen's series with acute massive hemorrhage, only 20 died. Of these 20 fatal cases, 12 bled to death without operative interference and 8 succumbed after operation. Complete failure of operation may be ascribed to intervention when the patient was in a depleted state. It is difficult to watch patients hovering between life and death from hemorrhage without finally resorting to surgical measures of relief, but it must be appreciated that the majority of such patients recover spontaneously and that such a major operation as is proposed is of itself hazardous from superadded surgical shock and postoperative complications. Almost certain operative failure after depletion from rapidly repeated hemorrhage naturally raises the question of earlier intervention. The difficulty here is to determine in advance whether the patient will spontaneously recover or die. I am impressed with Allen's figures of the low mortality in patients under and the high mortality in those over fifty years of age, and I should like to ask on how many cases in these age groups the figures are based. Though the chance of spontaneous recovery is much less in the older age group, I do not believe it is possible to predict whether or not spontaneous recovery will take place in the individual case. The attempt at selection is likely to lead to surgical intervention in certain patients who would recover without it. In view of the danger of an operation of such magnitude during an episode of severe bleeding, early interference is I think more likely to raise than to lower the mortality.

DR ALLEN There were forty-eight of these cases over fifty years of age with sixteen deaths, and ninety-one cases under fifty with four deaths. Perhaps these statistics are not important, but the fact remains that under fifty the chance of recovery is so great that we should treat them expectantly. If we could decide before these patients become so depleted that they are likely to fall into the mortality group, and operate on them as soon as they have recovered from shock and before they have become starved, a great many of them ought to be operated upon successfully. As a matter of fact we have radically operated upon them in a subacute stage quite successfully so far, twenty consecutive cases without mortality. I am perfectly sure however that the operative mortality after two or three weeks of hemorrhage and starvation must be very high, and that is I think the differential point. We must either operate early before the patients are depleted having made up our minds that they will fall into the high mortality group or hold out until they have recovered from the main effects of hemorrhagic depletion.

DR HOLMES May I ask Dr Allen whether in case he had had information as to where the

ulcer was it would have made any difference?

DR ALLEN If we had known it was a gastric and not a duodenal ulcer we should have operated just as soon as he had recovered from shock. I have a feeling that probably his severe postoperative pulmonary and wound infection would not have occurred if we could have operated upon him before he was actually starved to a level of no resistance. He was depleted by starvation as well as by bleeding.

DR EDWARD D CHURCHILL In relation to pneumonia, there is a term that comes to my mind in a picture like this, the so-called "aspiration pneumonia." It may also follow immersion, particularly in sewage contaminated waters. I shall expect to find multiple foci of pneumonitis with small abscesses, probably in the right lung a fairly good-sized one. I think the infection probably came from his mouth. The patient was vomiting and had been on restricted fluids by mouth before the operation. I am not certain that a film taken before the operation might not have shown this pneumonia. I think that when patients are kept on nothing by mouth for days the utmost care should be taken in oral hygiene, particularly if they are to face a surgical operation eventually.

DR CHESTER M JONES I have about the same feeling that Dr Allen has, that some of these patients must come inevitably to surgery, and any precautions we can take to insure better preoperative care should be taken. We have to accept the mortality in some of these cases rather than let them go. In this case I should say operation presented an unusually serious risk because of the age of the patient, and decision as to when to do it was harder here than in many cases we have had in the hospital.

CLINICAL DIAGNOSES (FROM HOSPITAL RECORD)

Bleeding gastric ulcer
Lung abscesses
Bronchopneumonia

ANATOMIC DIAGNOSES

Operative wound, posterior gastro-enterostomy, cauterization of ulcer of lesser curvature of stomach
Localized peritonitis
Multiple milary pulmonary abscesses
Chronic fibrous pleuritis
Operative wound, old appendectomy

PATHOLOGIC DISCUSSION

DR MALLORY The autopsy on this man showed of course the remnants of the ulcer, which was on the posterior wall of the stomach very close to the lesser curvature, partly involved the lesser curvature and had eroded a large vessel, as Dr Allen has told you. The floor of the ulcer was formed by the liver and pancreas, into both of which it had burrowed

fairly deeply. It would obviously be impossible to attempt resection of such an ulcer.

The peritoneal condition from which drainage persisted over such a long period proved to be a well localized peritonitis immediately under the postoperative wound and backed by the stomach and a portion of the liver. The greater part of the abdominal cavity was perfectly clean, I think it is quite fair to say that that had no significant part in causing his death.

The lungs showed a very uniform diffuse process consisting of multiple small abscesses not one of which was over half a centimeter in diameter. Microscopically these showed areas of increased leukocytic reaction.

No organisms except some very minute cocci could be made out, and no spirochetes were found, although a special spirochete stain has not been done.

The other organs were all essentially negative. The picture, as Dr Churchill suggested, is almost identical with that of what we call aspiration pneumonia. I have seen the same picture a number of times when there has been a definite history of vomiting during the later stages of anesthesia, and unquestionably inhalation does cause it. We have no such history here, unless the inhalation occurred before operation, which I think is very possible.

DR HOLMES There is one point which is difficult to explain, that is the disappearance of the process from the left lung after it had started, as far as I can tell by x-ray.

DR MALLORY Yes, there was no apparent difference in the type of the process or the age of the process on the two sides. The abscesses were in the terminal bronchioles and immediately adjacent alveoli, distributed by the bronchial tree and not by the blood vessels.

DR HOLMES Instead of saying that the x-rays were at fault, I said that he had had a disease from which he recovered, and the terminal picture was superimposed upon the early process. That would hardly be possible?

DR MALLORY I think it is possible that the process could have cleared up to some extent during a temporary period.

DR JONES That would fit into the clinical picture certainly.

DR HOLMES May I add that there is rather more fear of the barium meal in bleeding cases than is necessary. In such a case as this, barium could have been given and the ulcer located without danger to the patient.

CASE 20162

PRESENTATION OF CASE

An American clerk forty eight years old was admitted from a State prison for the repair of a ventral hernia.

Five years before entry he had an appendectomy, followed four months later by bulging of the lower end of the scar. Three years before entry he was told during a life insurance examination that he had bilateral inguinal hernia, although he had never noticed any swelling before.

His father died of heart failure at the age of seventy-four. His mother, who was seventy-four years old, was living, but in poor health. Two sisters were living and well. There was no history of tuberculosis or cancer.

He had been married for twenty-four years. His wife and four children were living and well. One child died following appendicitis. There had been one stillbirth.

He had been well most of his life. There was no history of scarlet fever, rheumatic fever, pneumonia or influenza. He was said to have had a traumatic pleurisy four years before admission, at which time two ribs were broken. Two years before entry he lost about twenty-five pounds but had gained forty-five pounds since that time. Recently he had lost about ten pounds.

Physical examination showed a healthy appearing, well nourished man. The upper teeth were false. There was some prorrhea. The abdomen was pendulous. There was marked protrusion in the right lower quadrant. Just to the right of the umbilicus was a scar at the distal end of which was a small easily reducible hernia. There was a small soft easily reducible right inguinal mass protruding down the inguinal canal and descending to two centimeters above the pubic spine.

The temperature was 98°, the pulse 80, the respiration 20.

Examination of the urine was negative. A Hinton test was negative. The non-protein nitrogen was 27. A preoperative white cell count was 12,300.

Three days after admission a ventral and a right direct inguinal hernia was repaired under gas and ether anesthesia. Two days after operation the patient developed what was called collapse at the right base. One week after operation his temperature was 101°. The signs in the right chest were still present and appeared more marked. There was dullness with diminished tubular breath sounds and voice sounds. A chest film on the sixteenth day showed in the right base a small triangular shadow of increased density with its apex directed toward the heart. There was slight displacement of the heart and mediastinum to the right. The supracardiac shadow was also increased to the right. His temperature remained elevated, ranging from 100° to 102°. He began to complain of sharp pains in the right chest anteriorly on deep inspiration, and also

produced a fair amount of sputum. On the twenty-seventh day a note was made that the chest pain had disappeared. His temperature still fluctuated up to 102°. He sweat profusely and brought up large amounts of purulent sputum. There was questionable early grooving of the nails.

X-ray examination of the chest at this time in the lateral view showed the dullness to lie in the midportion of the chest. It appeared to involve the anterior portion of the lower lobe and a portion of the middle lobe. The septum between the middle and upper lobes appeared to be displaced downward. No fluid levels were demonstrated.

Examination of the sputum showed Gram-positive and negative organisms and a rare spirochete. The sputum was thick, yellowish and definitely purulent. The amount varied between one and two ounces.

On the thirty-third day a diagnostic chest tap was performed with the removal of 50 cubic centimeters of greenish cloudy fluid with a specific gravity of 1.030. The cell count showed 2000 white blood cells and 200 red blood cells. A culture showed pneumococci (?). No bile solubility test was done. Two days later a trocar thoracotomy was performed with removal of similar fluid. Culture at this time showed non-hemolytic anaerobic streptococci. His temperature ranged in the neighborhood of 103°. He did poorly.

On the forty-eighth day incision and drainage of a chest wall abscess was performed. Thick foul pus was found overlying the rib in the posterior axillary line. An anterior extension of the incision was then made and a large phlegmon of the chest wall lying deep to the muscles was drained. There was no evidence of perforation of the pleura. The wound of the trocar thoracotomy was then explored and found to be undetermined, although by making a lateral incision better drainage was obtained there.

A white blood cell count at this time showed 42,000 cells. The red blood cell count was 5,100,000, with a hemoglobin of 70 per cent. He continued to do poorly. During the next month he received four transfusions. In the early part of the third month he developed edema of his legs. The serum proteins however were 6.7 per cent. The non-protein nitrogen was 37, the chlorides 575, and the carbon dioxide combining power 50.1 volumes per cent. His temperature continued to swing between 101° and 102°. On the ninety-second day lipiodol was injected into the apparent empyema cavity. A chest film showed partial collapse of the upper and middle lobes and complete collapse of the lower lobe. After the lipiodol injection a large cavity was visible just above the diaphragm extending to the right border of the heart from the axillary border and showing a definite fluid level. He continued to receive transfusions, but remained feb-

ulcer was it would have made any difference?

DR ALLEN If we had known it was a gastric and not a duodenal ulcer we should have operated just as soon as he had recovered from shock. I have a feeling that probably his severe postoperative pulmonary and wound infection would not have occurred if we could have operated upon him before he was actually starved to a level of no resistance. He was depleted by starvation as well as by bleeding.

DR EDWARD D CHURCHILL In relation to pneumonia, there is a term that comes to my mind in a picture like this, the so-called "aspiration pneumonia." It may also follow immersion, particularly in sewage contaminated waters. I shall expect to find multiple foci of pneumonitis with small abscesses, probably in the right lung a fairly good-sized one. I think the infection probably came from his mouth. The patient was vomiting and had been on restricted fluids by mouth before the operation. I am not certain that a film taken before the operation might not have shown this pneumonia. I think that when patients are kept on nothing by mouth for days the utmost care should be taken in oral hygiene, particularly if they are to face a surgical operation eventually.

DR CHESTER M JONES I have about the same feeling that Dr Allen has, that some of these patients must come inevitably to surgery, and any precautions we can take to insure better preoperative care should be taken. We have to accept the mortality in some of these cases rather than let them go. In this case I should say operation presented an unusually serious risk because of the age of the patient, and decision as to when to do it was harder here than in many cases we have had in the hospital.

CLINICAL DIAGNOSES (FROM HOSPITAL RECORD)

Bleeding gastric ulcer
Lung abscesses
Bronchopneumonia

ANATOMIC DIAGNOSES

Operative wound, posterior gastro enterostomy, cauterization of ulcer of lesser curvature of stomach
Localized peritonitis
Multiple miliary pulmonary abscesses
Chronic fibrous pleuritis
Operative wound, old appendectomy

PATHOLOGIC DISCUSSION

DR MALLORY The autopsy on this man showed of course the remnants of the ulcer, which was on the posterior wall of the stomach very close to the lesser curvature, partly involved the lesser curvature and had eroded a large vessel, as Dr Allen has told you. The floor of the ulcer was formed by the liver and pancreas, into both of which it had burrowed

fairly deeply. It would obviously be impossible to attempt resection of such an ulcer.

The peritoneal condition from which drainage persisted over such a long period proved to be a well localized peritonitis immediately under the postoperative wound and backed by the stomach and a portion of the liver. The greater part of the abdominal cavity was perfectly clean, I think it is quite fair to say that that had no significant part in causing his death.

The lungs showed a very uniform diffuse process consisting of multiple small abscesses not one of which was over half a centimeter in diameter. Microscopically these showed areas of increased leukocytic reaction.

No organisms except some very minute cocci could be made out, and no spirochetes were found, although a special spirochete stain has not been done.

The other organs were all essentially negative.

The picture, as Dr Churchill suggested, is almost identical with that of what we call aspiration pneumonia. I have seen the same picture a number of times when there has been a definite history of vomiting during the later stages of anesthesia, and unquestionably inhalation does cause it. We have no such history here, unless the inhalation occurred before operation, which I think is very possible.

DR HOLMES There is one point which is difficult to explain, that is the disappearance of the process from the left lung after it had started, as far as I can tell by x-ray.

DR MALLORY Yes, there was no apparent difference in the type of the process or the age of the process on the two sides. The abscesses were in the terminal bronchioles and immediately adjacent alveoli, distributed by the bronchial tree and not by the blood vessels.

DR HOLMES Instead of saying that the x-rays were at fault, I said that he had had a disease from which he recovered, and the terminal picture was superimposed upon the early process. That would hardly be possible?

DR MALLORY I think it is possible that the process could have cleared up to some extent during a temporary period.

DR JONES That would fit into the clinical picture certainly.

DR HOLMES May I add that there is rather more fear of the barium meal in bleeding cases than is necessary. In such a case as this, barium could have been given and the ulcer located without danger to the patient.

CASE 20162

PRESENTATION OF CASE

An American clerk forty-eight years old was admitted from a State prison for the repair of a ventral hernia.

rule, gradually failed, and died approximately sixteen weeks after admission

CLINICAL DISCUSSION

DR. GEORGE W. HOLMES: These are the earlier films. They show a process in the right lower lobe which is certainly not characteristic of collapse, although apparently that is what it was thought to be at the time. There is some elevation of the diaphragm, no displacement of the heart.

In the lateral view the process seems to be in the middle lobe. We can have collapse of the middle lobe without much displacement, but the appearance here is more like consolidation. You must remember that we attempt always to take the films at full inspiration, and with pneumonia on one side the diaphragm is always going to be higher on the side where the process is, because that lung does not fill, so that elevation of the diaphragm does not necessarily mean collapse. If this film had been taken at expiration there would not be that difference.

This film I presume was taken at the time the trocar thoracotomy was done. You can see the position of the partially collapsed lung and the fluid along the axillary border. A little later the border of the collapsed lung is better seen. The area of consolidation is still present. There is an area of rarefaction along the axillary border. The extreme base is quite dull, and there is mottled dullness extending upward into the partially collapsed lung.

This film was taken on the same day as the one that I have just shown you. The process is still confined to the right lung.

DR. FREDERICK T. LORD: There is very little for me to add. In the Thoracic Clinic we made a diagnosis of lung suppuration with empyema. He probably had a peripheral abscess draining into the pleural cavity. We have had a number of instances of the relief of pulmonary abscess by drainage of empyema.

DR. DONALD S. KING: I only wish to say that abscess is the unusual type of postoperative complication. The percentage is low.

DR. CHESTER M. JONES: I was asked to say why he had edema, and it seemed to me quite clear that it was associated with long continued sepsis. Whether the edema was actually due to undernutrition incident to the sepsis and therefore a starvation edema complicated by prolonged sepsis and subsequent loss of protein, or due to amyloid changes resulting from chronic sepsis, I was unable to determine. The former explanation is the more likely.

DR. EDWARD D. CHURCHILL: The chronicity of the disease in these two cases is interesting—four months' duration in one, twenty-nine days in the other. The organisms that seemed to be the underlying cause in both cases work very slowly and relentlessly. We see them in action externally from time to time in human bite in-

fections of the hand. They are particularly fatal and unyielding when the lung and chest wall are invaded.

DR. TRACY B. MALLORY: Does not the usual case of this type if it lasts as long as this result in a pretty obvious, well-defined abscess?

DR. CHURCHILL: If it stays within the lung. This type of infection usually extends to the pleura.

CLINICAL DIAGNOSES

Right inguinal, umbilical and ventral herniae
Chronic empyema
Lung abscess

ANATOMIC DIAGNOSES

Pulmonary tuberculosis, acute, right
Tuberculous pneumonia, right
Empyema, right
Subacute glomerular nephritis
Miliary tuberculosis of the liver and spleen.
Pulmonary tuberculosis, healed, left
Pulmonary edema, left
Pleuritis, chronic fibrous, right
Arteriosclerosis, slight, aortic and coronary
Cholelithiasis

PATHOLOGIC DISCUSSION

DR. MALLORY: The autopsy on this man presented a surprise. There was of course an empyema and a small abscess cavity which drained into it, but I do not believe that was the cause of his death. He died of a diffuse tuberculous pneumonia. In the four months he was in the hospital, so far as I can make out from the record, no examination was made for acid-fast bacilli. The process was a very atypical one and was not recognized in gross at the time of autopsy, but, when the slides came through, the liver was found to be peppered with miliary tubercles, and acid-fast stains in the lung show plenty of the organisms.

In connection with his edema, undoubtedly the low serum albumin had a great deal to do with it, but he did have a well-marked nephritis, a glomerulonephritis in spite of the lack of rise in the non-protein nitrogen.

DR. JONES: Did he have any amyloid deposits?

DR. MALLORY: No.

DR. CHURCHILL: Were the lungs studded with miliary tubercles?

DR. MALLORY: The lesions in the lungs are quite large. Here is one of them, a big area of caseation with central necrosis. In gross they were all of them mistaken for abscesses, but as one gets out to the periphery of each lesion one begins to find small tubercles. There were large areas of typical caseous pneumonia. One focus of old tuberculosis, evidently long antedating the present infection, was found. Miliary tubercles were present not only in the liver but also in the spleen, and a few scattered ones in the kidney.

A CHALLENGE TO THE MEDICAL PROFESSION

DURING recent years much attention has been given to the possibilities of the practice of preventive medicine in the office of the family physician. Opinion both within and without the medical profession has been unanimous in the belief that this should be developed as extensively as possible differences of opinion arising only as to the degree to which privately and publicly supported clinics should supplement this service. Timely in this connection is the letter recently sent by the Department of Public Health to all physicians in the State, emphasizing the opportunities that are theirs for the further use of diphtheria immunization in their private practice. Particularly significant in this letter is the statement that were immunization made a routine part of the care of the infant "there would be little need for the continuance of public clinics"

This statement may well be accepted as a direct challenge to the medical profession. Statistics of the public immunization clinics show that the majority of the children thus treated are already of school age. Were diphtheria of concern only to the school child, this might be sound practice. When it is remembered, however that two-thirds of the diphtheria deaths occur in children of preschool age it is readily apparent that the bulk of the publicly supported immunization work is merely to compensate for the omissions of private practice. The family physician has had five years during which he might have immunized the child, and yet in too many instances he has not availed himself of this opportunity. No health department is anxious to carry on immunization work, but, to protect the children of the community, must provide for this if so high a proportion of children are not reached by the family physicians. The extent of the clinic patronage is largely, therefore, a problem which rests in the hands of the medical profession.

Likewise of significance is the tabulation that accompanied the letter showing the prevalence of diphtheria in the larger communities. The city of Lowell, and more particularly the board of health and the physicians, can take no pride in its unenviable distinction of having the highest diphtheria rate in the state. When it is remembered that this is but a repetition of the same unenviable record in 1932 when Lowell was in this respect supreme in New England and a close contender for these questionable laurels on a nation-wide basis, it is evident that it behooves the authorities to do more than condone the situation. This problem may well merit the best attention of the Lowell medical profession. It is to be hoped also that Lowell's chief rivals, New Bedford, Medford, and Somerville, will similarly accept the challenge which these figures convey. In Weymouth it was met too late in the year to affect the figures, but was met by such cooperation between the physicians and the school as to leave no question as to the result. It may well behoove the other communities to do likewise, remembering always, however, that this is but a poor substitute for immunization carried on by the family physician as a part of the routine care of the first year of life.

IODINE AS AN ANTISEPTIC

DURING the past five or ten years, so many claims have been made by the manufacturers of antiseptic solutions that the physician is at a loss to know what to use in his own practice and what is best to advise for use in the homes of his patients. The relative value of such solutions must be based, primarily, on their ability

rile, gradually failed, and died approximately sixteen weeks after admission

CLINICAL DISCUSSION

DR GEORGE W HOLMES These are the earlier films. They show a process in the right lower lobe which is certainly not characteristic of collapse, although apparently that is what it was thought to be at the time. There is some elevation of the diaphragm, no displacement of the heart.

In the lateral view the process seems to be in the middle lobe. We can have collapse of the middle lobe without much displacement, but the appearance here is more like consolidation. You must remember that we attempt always to take the films at full inspiration, and with pneumonia on one side the diaphragm is always going to be higher on the side where the process is because that lung does not fill, so that elevation of the diaphragm does not necessarily mean collapse. If this film had been taken at expiration there would not be that difference.

This film I presume was taken at the time the trocar thoracotomy was done. You can see the position of the partially collapsed lung and the fluid along the axillary border. A little later the border of the collapsed lung is better seen. The area of consolidation is still present. There is an area of rarefaction along the axillary border. The extreme base is quite dull, and there is mottled dullness extending upward into the partially collapsed lung.

This film was taken on the same day as the one that I have just shown you. The process is still confined to the right lung.

DR FREDERICK T LORD There is very little for me to add. In the Thoracic Clinic we made a diagnosis of lung suppuration with empyema. He probably had a peripheral abscess draining into the pleural cavity. We have had a number of instances of the relief of pulmonary abscess by drainage of empyema.

DR DONALD S KING I only wish to say that abscess is the unusual type of postoperative complication. The percentage is low.

DR CHESTER M JONES I was asked to say why he had edema, and it seemed to me quite clear that it was associated with long continued sepsis. Whether the edema was actually due to undernutrition incident to the sepsis and therefore a starvation edema complicated by prolonged sepsis and subsequent loss of protein, or due to amyloid changes resulting from chronic sepsis, I was unable to determine. The former explanation is the more likely.

DR EDWARD D CHURCHILL The chronicity of the disease in these two cases is interesting—four months' duration in one, twenty-nine days in the other. The organisms that seemed to be the underlying cause in both cases work very slowly and relentlessly. We see them in action externally from time to time in human bite in-

fections of the hand. They are particularly fatal and unyielding when the lung and chest wall are invaded.

DR TRACY B MALLORY Does not the usual case of this type if it lasts as long as this result in a pretty obvious, well defined abscess?

DR CHURCHILL If it stays within the lung. This type of infection usually extends to the pleura.

MISCELLANY

RECOMMENDATIONS OF THE COMMITTEE APPOINTED BY THE MAYOR OF BOSTON TO SURVEY THE HEALTH DEPARTMENT—MARCH 24 1934*

The various reductions in the budget items which we have indicated can only be secured by a reorganization of the Health Department, with consolidation of divisions and curtailment of certain activities In order to secure a more effective, closely

From a copy sent by His Honor the Mayor to the Boston Health League.

knit, well coordinated organization, we wish to make the following recommendations

ADMINISTRATION

We Recommend

1 That an official Public Health Council of five persons familiar with public health functions and public health administrative methods be selected by the Mayor. These persons should serve without compensation for a term of five years, with overlapping terms of office. They should hold monthly meetings and should advise the Health Commissioner on the policies of the Department, the appointment of personnel, and should pass on the annual budget.

We Recommend

2 That the Health Department should be reorganized into six major divisions, as follows

- A Administration, including Accounts, Vital Statistics and Health Education
- B Communicable Disease
- C Child Hygiene
- D Sanitation
- E Public Health Nursing
- F Laboratories

The Commissioner should be administrative officer for all the departments and responsible to the Mayor for the effectiveness of his work. He should have direct charge of the *Division of Administration*. There should be but one Deputy Commissioner, all other titles of Deputy Commissioner should be abolished. The Deputy Commissioner may well have direct responsibility for administration of the Health Centers and also the *Division of Child Hygiene*.

There should be one director for each of the major divisions that we have listed above. Each director should be responsible to the Commissioner for the activities of his division. Each divisional director should be thoroughly qualified to carry out the functions assigned to him and should devote his *full time* to the work of the Health Department.

MEDICAL DIVISION

We Recommend

3 That the term "Medical Division" be changed and the division be called the "Division of Communicable Disease Control."

The present functions and activities of the *Division of Tuberculosis* should be merged with this division.

One-half the cost of the medical inspectors that are assigned to the Health Centers should be charged to this division.

We Recommend

4 That the Detention Hospital be closed. It is an unnecessary expense and serves no practical purpose. All necessary hospitalization of contagious disease should be assigned to the contagious disease wards of the Boston City Hospital.

CHILD HYGIENE

We Recommend

5 That the Health Centers be strengthened and

supported, for they represent real health protection and promotion to the citizens of Boston. These eight Health Centers are the very life of the Health Department and are Boston's greatest contribution to public health administration in the United States.

SANITATION

We Recommend

6 That all functions relating to sanitation should be fused in a single *Division of Sanitation*. To this division should be assigned all activities relating to food inspection, abattoir service, dairy inspection service, milk inspection service and general sanitation.

We Recommend

7 That the dairy inspection service be transferred to the State. The new State law has already made provision for this function. The members of this division may be transferred directly to the State Milk Regulation Board as soon as funds are provided in the supplementary budget.

We Recommend

8 That a marked curtailment of activities and a reduction in personnel of the Division of Sanitation be made. Most of the activities of this department bear no relationship whatever to protection of the health of the city, are a relic of the past, and are not public health functions.

We Recommend

9 That the Convenience Station service be transferred to some other division of city government. This service is not a function of the Department of Public Health and should not be allocated to its budget.

PUBLIC HEALTH NURSING

The Public Health Nursing Division has a larger personnel and budget than any other division. Nevertheless, the existing staff is not sufficient to carry out the usual volume of public health nursing service for a population of 800,000. This is indicated in the following comparison:

Staff necessary according to the usual volume of public health nursing service for 800,000 people	1933 staff of public health nurses employed by the City Health Department in Boston
1 Director and 1 Assistant	1 Director, no Assistant
13 Supervisors	11 Supervisors
131 Staff Nurses	117 Staff Nurses
4 Nutrition Workers	2 Nutrition Workers (2 Assistants)
2 Mental Hygiene Workers	No Mental Hygiene Workers
Clerical—1 clerk for 10-12 nurses	2 Clerks

Despite the fact that Boston does not have adequate public health nursing personnel, we can see no alternative under the existing emergency than to cut the personnel.

We Recommend

- 10 A reduction in the nursing personnel of
2 Supervisors
1 Nutrition Worker
2 Assistant Nutritionists
8 Nurses attached to the Health Centers
7 Field Nurses

The nurses removed from the Health Centers need not necessarily be the persons dismissed. It would seem advisable to reduce the staff first by those persons for whom new positions were created in 1933, secondly at the discretion of the director remove those persons who give least adequate service and are the least satisfactory. This would hold good in relation to the staff and the supervisors. Another consideration would be naturally those nurses who had other means of support.

LABORATORY**We Recommend**

- 11 That the salaries of all personnel engaged in laboratory work or related activities be allocated to the Division of Laboratories

When dairy inspection service is transferred to the State, it may be necessary for the laboratory to do more intensive milk analysis work so that a slight increase in the laboratory budget may be necessary.

HOSPITALIZATION OF TUBERCULOSIS**We Recommend**

- 12 That no substantial reduction be made in the item for hospitalization of cases of tuberculosis. The present waiting list for hospitalization shows the need for these funds. More intensive clinic work will probably result in a reduction of this item in the very near future.

Committee

WILSON G. SMILLIE, M.D.
PROFESSOR CLAIR E. TURNER,
SOPHIE C. NELSON, R.N.

DR. GEORGE W. HAWLEY'S FRACTURE TABLE

The man who twenty years ago invented the world's first orthopedic and fracture table, and whose work has since won him renown throughout the civilized world has now made an even greater contribution to his fellow man—and he has done it while bedridden at Glockner Sanatorium in Colorado Springs, Colorado.

He is Dr. George W. Hawley of Bridgeport, Conn., who has been decorated by foreign countries and is regarded as one of the world's authorities on fractures. He has been a member of the fracture committee of the American College of Surgeons ever since it was created. During the World War he was in charge of America's only bone and joint hospital in France.

Three years ago tuberculosis undermined Dr. Hawley's health and he was sent to Glockner Sanatorium, which is at the base of Pike's Peak. Unable to carry on his practice he converted his hospital room into a makeshift laboratory and from his bed directed experiments. Engineers traveled across the continent to confer with him in bringing out a new fracture table that combines the x-ray and fluoroscope with it for the first time in medical history.

The table is not yet in general use but it is installed in some of the leading hospitals in India, Belgium, Philadelphia, New York City, Atlanta, Ga., Sharon, Pa., Washington, D. C., Milwaukee, Wis., Toledo, O., Waukesha, Wis., Elmira, N. Y., Ogden, Utah, and Glockner hospital in Colorado Springs where the original was perfected.

Guesswork in setting fractured bones has been entirely eliminated through the use of the new table which permits the surgeon to watch and guide the fracture ends during reduction, through the fluoroscope. He is not compelled to manipulate and attempt reduction blindly and then take radiographs to learn whether the operation is complete or a failure. In the past, treatment of fractures required the help of many hands, extravagance of costly dressings and in instances the job had to be done over.

Formerly the patient was subjected to much pain and handling by being moved from the fracture table to the x-ray table. With the new combination table and x-ray the surgeon may take radiographs of any type of fracture at any time during the operation regardless of the position of the patient. This is possible because of the design of the apparatus and the mobile shock-proof x-ray unit. There is no danger to the patient, nor the surgeon from possible shock. The table is of steel with top sections of plywood covered with bakelite, permitting free passage of the x-ray and eliminating graining of radiographs.

Doctors say that the new table not only revolutionizes and simplifies handling of fracture cases but is a more humane and more economical apparatus and procedure.

Dr. Hawley's table that was brought out twenty years ago is now in the Smithsonian Institution, Washington, D. C.

While Dr. Hawley has been at work on the new table he has been cured seemingly a reward for his effort. He has recently been released from the Colorado Springs Hospital.

CORRESPONDENCE

DIPHTHERIA PREVENTION

The Commonwealth of Massachusetts
Department of Public Health
State House, Boston

March 21, 1934

Dear Doctor

In 1933 there were only 1,041 cases and 86 deaths from diphtheria as contrasted with 9,018 cases and 579 deaths in 1923. Great as may be our satisfaction at this striking reduction, much remains to be done in diphtheria prevention. The greatest opportunity for diphtheria immunization in the future rests in the hands of the family physician. Many physicians today regularly immunize all infants under their care. Were this done routinely by all physicians in the State, diphtheria would soon virtually disappear, and there would be little need for the continuance of public clinics.

May we bespeak your cooperation and interest in this work. The advisability of immunization should be called to the attention of all parents and active immunization with diphtheria toxoid should be recommended as a routine during the latter half of the first year of life. The Department of Public Health urges all boards of health to send a card similar to the enclosed, on the basis of birth records. If your community is not already doing so, we would suggest that you take this up with your board of health. There is enclosed also a table showing the incidence of diphtheria in the larger cities and towns during the past few years. Only

by constant effort can the reduction already achieved be maintained.

Very truly yours,

HENRY D. CHADWICK, M.D.,
Commissioner of Public Health,
WILLIAM H. ROBESY, M.D.,
President, Massachusetts Medical
Society,
DWIGHT O'HARA, M.D.,
Chairman, Committee of Public
Health, Massachusetts Medi-
cal Society

A SAMPLE OF THE CARD

The Commonwealth of Massachusetts
Department of Public Health

Diphtheria Can Be Prevented

The ideal time to protect a child against diphtheria is between the ages of six months and one year. Our records show that your baby is now over six months old. We therefore urge you to take this matter up with your family physician at your earliest opportunity. Every case of diphtheria is unnecessary and could be avoided by immunization.

Board of Health of _____

and

Massachusetts Department of Public Health

I have immunized _____ against diphtheria.
Please bring this child back in six months for a
Schick test.

RECENT DEATHS

PERRY—**MARTHA PERRY, M.D.**, died in New Bedford, March 29, 1934, at the age of ninety-three years. She graduated from Mt Holyoke, and the Woman's Medical College of Pennsylvania where she served as an interne.

Dr Perry joined the Massachusetts Medical Society in 1885 and retired in 1913.

During her thirty-five years of practice in Taunton, she served as trustee, clerk, and member of the Staff of the Morton Hospital.

Dr Perry was a member of the Congregational Church and was active in civic affairs.

Burial was at West Yarmouth.

SOLBY—**IRVING SOLBY, M.D.**, of 235 Chestnut Hill Avenue, Brighton, Massachusetts, died suddenly, March 26, 1934. He was a native of Northampton, Massachusetts, a graduate of Amherst College and from the Harvard University Medical School in 1907. He retired from practice several years ago and en-

gaged in business. He joined the Massachusetts Medical Society in 1908 under the name of Sobotky and retired in 1924. He is survived by his widow, Mrs. Wilhelmina Soiby, and his mother, Mrs. Rose Sobotky.

McGAURAN—**MICHAEL SHERIDAN McGAURAN, M.D.**, of Lawrence, Massachusetts, died March 25, 1934. He was born in 1847. He graduated in medicine from the Rush Medical College of Chicago in 1888. He joined the Massachusetts Medical Society in 1891 and retired in 1927.

His interest in local organizations is shown by the following designated bequests in his will: St. Mary's Parochial School, Lawrence, \$1000 for prizes; Salvation Army, Lawrence, \$200; Working Boys' Home, Newton, \$1000; Lawrence Orphan Asylum, \$1000.

OBITUARY

L MAUD CARVILL, M.D.

In the recent death of Dr. L. Maud Carvill the community has lost a skilled ophthalmologist and a noble woman. Herself the daughter of a physician, she carried on the old tradition which makes the practice of medicine a career of self-sacrifice.

She graduated from the Sargent Normal School of Physical Training in 1895, receiving her A.B. from Tufts College in 1899, and her M.D. from the same college in 1905. She rose rapidly in her chosen specialty and became an assistant surgeon in ophthalmology at the Massachusetts Eye and Ear Infirmary and the Massachusetts General Hospital. From this position she retired a year ago. She served also as Visiting Ophthalmologist to the New England Hospital for Women and Children for over twenty years, retiring in 1929 to become a consultant.

She belonged to such general organizations as the New England Women's Medical Society, the Massachusetts Medical Society, and the American Medical Association. Of the societies demanding special training and achievement, she held membership in the New England Ophthalmological Society, the American College of Surgeons, the American Academy of Ophthalmology and Otolaryngology, and the American Ophthalmological Society. Of the last named society she was the only woman member, winning admission by a thesis on glaucoma. Through this paper she became nationally recognized as an authority on the subject. She is cited as one of the American authorities on two other subjects as well, interstitial keratitis and tuberculosis of the eye. At the International Congress of Ophthalmologists in Washington in 1922 she presented a paper entitled 'Bitemporal Contraction of the Visual Fields in Pregnancy' a contribution which has become a classic in the subject in Europe as well as America. Minor articles of hers are entitled 'A Contribution to the Study of Phlyctenular Keratitis' and 'Persistent Hyaloid Artery'. From

the material of an arduous practice she was constantly drawing conclusions and publishing them as scientific papers. As a result of these labors she has been estimated by a noted colleague as the most outstanding American woman of her generation in ophthalmological research.

Dr Carvill would have found herself appalled in the presence of this summary of her achievements for she suffered from a painful modesty which minimized the value of whatever she did. Reticence pervaded all the deeper ranges of her life in religion, in friendship, in family relations. She was a woman of more deeds than words. A touch of Puritan austerity demanded nothing short of the best, of herself and everyone else but it was meliorated by humor and a great kindness. Her total honesty in the face of facts made her essentially a scientist, but she was always as well a ministering physician. For six months she faced imminent death with entire fortitude, asking only to be spared long enough to complete her immediate tasks. This was granted her.

To a host of patients Dr Carvill leaves the fragrance of a grateful memory. For her associates in medicine, she lays on their personal loss the healing touch of a desire for better work and more exacting living.

NOTICES

A CLINIC ON PNEUMONIA

On Thursday afternoon April 26 at 3 30 P.M., in the amphitheater of the Peter Bent Brigham Hospital Dr Alfred Stengel, Professor of Medicine and Vice President in charge of Medical Affairs at the University of Pennsylvania. Physician in Chief *pro tempore* at the Peter Bent Brigham Hospital will give a clinic on pneumothorax in the treatment of pneumonia. Students of medicine and practicing physicians are invited to attend.

HENRY A. CHRISTIAN, M.D.

THE AMERICAN BOARD OF DERMATOLOGY AND SYPHILOLOGY

EXAMINATIONS FOR CERTIFICATES

The American Board of Dermatology and Syphilology will hold written examinations for candidates for a certificate on April 30 1934 in the following cities: New York City St. Louis Mo. Boston Mass. Cleveland Ohio San Francisco Calif. Philadelphia Pa. and Chicago Ill.

If a sufficient number of applicants register for the examination from other districts additional examinations will be held in other cities. This examination will be for applicants in both Group A and Group B.

The oral examination for both Group A and Group B will be held in Cleveland Ohio June 11 and 12 at the time of the American Medical Association meeting.

Further information may be obtained from the Secretary Dr C Gny Lane, 416 Marlboro Street, Boston, Mass.

PHYSICIANS' ART EXHIBIT

The Exhibit will open on Monday April 23, at the Boston Medical Library and continue through Saturday, May 5. The hours will be from 10 A.M. to 6 P.M. daily and 7 to 10 P.M. on Monday and Wednesday evenings.

Great interest is being shown in the exhibit and more pictures and models have been received than it will be possible to hang or display.

Through the kindness of an anonymous donor who is greatly interested in the advancement of art among the members of the medical profession, an award will be made for the best example of creative art. The award will be made by a committee of well known Boston artists who will also make selections for the exhibit to be held in October at the time of the meeting of the American College of Surgeons.

REPORT AND NOTICES OF MEETINGS

NEW ENGLAND HEART ASSOCIATION

The New England Heart Association held a meeting on Monday, March 26 in the Evans Auditorium of the Massachusetts Memorial Hospitals with Dr W D Reid presiding.

The program began with a talk by Dr George Levene on the roentgenologic diagnosis of coronary disease. The left ventricle is measured by a line extending from the auriculoventricular junction to the apex of the heart. A perpendicular to this line, erected at the point of greatest curve of the left heart border shows the thickness of the left ventricular myocardium which normally measures between eight and ten millimeters. This thickness is due to the amount and tone of the heart muscle.

The circumflex and anterior descending branches of the left coronary artery are the ones most frequently and extensively involved. Since these are distributed to that portion of the heart muscle which forms its left contour disease of these vessels readily manifests itself by changes in the appearance and activity of the left border.

The thickness of the left ventricular myocardium becomes diminished due to a loss of tone and frequently to degeneration of the muscle fibers. The heart appears to sag. Fluoroscopically the amplitude of pulsations is greatly diminished and when infarction is present, the amplitude of pulsations in the ventricle is weaker than those of the auricle. These findings have frequently enabled the speaker to diagnose coronary disease without any clinical knowledge of the patient. Demonstration of calc

fication of the coronary arteries is a diagnostic point of lesser importance, since it occurs infrequently and too late to be of practical clinical value

Dr Richard J Wagner presented a paper with lantern slides on carbohydrate metabolism in hypertension. This is part of a metabolic study now in progress at the Evans Memorial. Liver function was found disturbed in 80 per cent of the cases presented. Ten per cent of the cases showed a diabetic sugar tolerance curve. In 46 per cent of the hypertension cases the specific dynamic effect of carbohydrates was not present. In these cases the oxygen consumption did not rise after 100 Gm of sugar were given, but remained practically at the basal level, whereas in the remaining 44 per cent of all cases, the specific dynamic effect was present as in normal individuals, and a rise of the oxygen consumption after the sugar test meal from 300 to 800 calories was determined. The blood pressure declined in most of the cases of the group without specific dynamic effect from 20 to 80 mm systolic and 10 to 40 mm diastolic. In the group with normal response to the sugar stimulus only a small percentage did show a drop of the pressure. An increase of the urinary nitrogen output was observed in most of the cases without pressure response to the sugar meal. In the cases without pressure response the nitrogen output remained constant or was somewhat decreased. His work shows that the carbohydrate metabolism plays an important rôle in diseases which have hypertension as one symptom.

Dr Walter Mendenhall, professor of pharmacology of the Boston University Medical School, talked on certain drugs included in the curriculum but rarely used by the medical profession. These drugs included veratrum, salol, picrotoxin, pilocarpine, and curare. Veratrum has never been used to any great extent yet it is known to be a stimulant of the vagus center and can be given in doses that are not toxic. Salol, he believes, deserves to be tried in rheumatic fever and muscular pains as it contains salicylates in a form not irritating to the stomach. Pilocarpine a stimulant of the autonomic system, could be used more to moisten the mucous membranes and to remove fluids in cases of generalized edema. Picrotoxin until recently was seldom if ever used, but today it is used a great deal in the treatment of sodium amyl poisoning.

Dr Samuel H. Caldwell of the Department of Electrical Engineering at the Massachusetts Institute of Technology gave a demonstration lecture on electric oscillations and their significance in electrocardiography. He stated that the waves in an electrocardiogram are the summation of a number of waves. In other words, each wave can be broken down into a fundamental wave and a series of harmonics, or higher frequency waves related to the fundamental one. The analysis of a typical wave into its components was demonstrated. Such analy-

sis discloses the presence of frequencies far in excess of those that the string galvanometer, as used in clinical electrocardiography, is capable of recording. The need, therefore, for apparatus that is capable of recording faithfully these high frequencies is obvious.

Dr Caldwell concluded his talk by operating a cathode ray oscillograph to demonstrate visibly the shape and composition of certain electrical waves. It was suggested that the cathode ray oscillograph has important application in laboratories devoted to medical science.

The meeting was concluded by a demonstration of the "Mechanical Hearts" invented by Dr George Levene. These working models show the heart as it actually appears under the fluoroscope. The display included the normal heart, more common arrhythmias, valvular lesions, thyrotoxicosis, and coronary disease. The device should be of great value in teaching and demonstrating heart disease.

MASSACHUSETTS PSYCHIATRIC SOCIETY

The next meeting of the Massachusetts Psychiatric Society will be held on Friday evening, April 20, at the Boston Psychopathic Hospital at 8 P M.

The scientific program is to be as follows:

"The Effects of the Alteration of Posture on the Cerebrospinal Fluid Pressure" Dr Julius Loman

"Mental Disease in a Tuberculosis Sanitarium Population" Dr Clifford Moore

OSOAR J. RAEDER, M.D., *Secretary*

SUFFOLK DISTRICT MEDICAL SOCIETY

CENSORS' MEETING

The Censors of the Suffolk District Medical Society will meet for the examination of candidates at the Boston Medical Library, No. 8 The Fenway, Thursday, May 3, 1934, at 4 00 o'clock.

Candidates should make personal application to the Secretary, and present their medical diploma at least one week before the examination.

GEORGE P. REYNOLDS, M.D., *Secretary*

311 Beacon Street, Boston

HARVARD MEDICAL SOCIETY

POSTPONEMENT OF MEETING

The meeting of the Harvard Medical Society, scheduled for April 24, to be addressed by Dr James C. White, has been postponed to May 8. Notice with title will appear later.

JOHN HOMANS, M.D., *Secretary*

HOUSE OFFICERS' ASSOCIATION OF THE BOSTON CITY HOSPITAL

Monday, April 23, 1934

Subject Gynaecology

8 00 P M Presentation of Cases

8 15 P M "What Should Be the Attitude of the Beginning Practitioner of Medicine Toward the Practice of Obstetrics" Frederick L. Good, M.D.

8 35 P.M. 'Endometriosis' Frank A. Pemberton, MD

8 55 P.M. "The Modern Understanding of Human Infertility" Samuel R. Meaker, M.D.

9 15 P.M. "Gonorrhea in Women as a Clinical Entity" Alonzo K. Paine M.D.

This meeting will be held at the Thorndike Amphitheatre at the Boston City Hospital.

ROBERT T. PHILLIPS, M.D., *Secretary*

NEW ENGLAND PHYSICAL THERAPY SOCIETY

The regular meeting of the New England Physical Therapy Society will be held, through the courtesy of Dr. Herbert E. Herrin, Superintendent, in the Lecture Hall of the Psychiatric Clinic, Boston State Hospital, at 7 45 P.M., April 24, 1934.

The program is in charge of Dr. Rebekah Wright, Hydrotherapist, Massachusetts Department of Mental Diseases.

PROGRAM

Hydrotherapy Rebekah Wright, M.D., Boston.

The Superintendents of three Massachusetts State Hospitals will speak briefly on

The Continuous Bath. Ralph M. Chambers, M.D., Taunton.

The Wet Sheet Pack. Edward W. Whitney, M.D., Northampton.

Colonic Irrigation. Charles E. Thompson, M.D., Gardner.

After a demonstration in the hydrotherapy suite, the members and guests will be shown the other physical therapy facilities of the Clinic and will return to the Lecture Hall for discussion.

At 7 30 o'clock, prior to the program, there will be a meeting of the Council. Councilors are urged to arrive promptly as nominations for officers of the Society will be made at this meeting.

All members of the medical profession are cordially invited to be present and to participate in the discussion.

ARTHUR H. RING, M.D., *Secretary*

HAMPDEN DISTRICT MEDICAL SOCIETY

The Annual Meeting of the Society will be held at Hotel Kimball, Springfield on Tuesday, April 24, 1934, at 4 P.M.

Regular business and election of officers for the ensuing year.

Paper for the afternoon "The Neuroses as the General Practitioner Meets Them" Dr. Abraham Myerson of Boston.

Discussion by Fellows.

Dinner at 6 P.M. at expense of Society.

HERVEY L. SMITH, *Secretary and Treasurer*

Censors meet for examination of candidates for admission to the Society in the rooms of the Springfield Academy of Medicine 20 Maple Street, Springfield, on Thursday, May 3, at 4 P.M.

WORCESTER NORTH DISTRICT MEDICAL SOCIETY

The annual meeting of the Worcester North District Medical Society will be held at the Burbank Hospital, Fitchburg, Mass., on Wednesday April 25, at one o'clock P.M. Dr. Andrew R. MacAusland of Boston will deliver the annual oration on 'Recent Trends in the Treatment of Fractures'. Officers for the year will be elected. Dinner will be furnished by the hospital management.

FRANCIS M. McMURRAY, M.D., *Secretary*

PHI DELTA EPSILON FRATERNITY

A late notice appears on page 882.

SOCIETY MEETINGS, CONGRESSES AND CONFERENCES

April 20 and 27—Salmon Memorial Lectures. See page 443 Issue of February 22.

April 20—New England Roentgen Ray Society will meet at the Beth Israel Hospital at 3 15 P.M.

April 20—Massachusetts Psychiatric Society. See page 373.

April 23—Phi Delta Epsilon Fraternity. See page 882.

April 23—New England Heart Association will meet in the Assembly Room of the House of the Good Samaritan at 3 15 P.M.

April 23—House Officers Association of the Boston City Hospital. See page 373.

April 23—May 5—Physicians Art Exhibit at the Boston Medical Library 8 The Fenway. See page 377.

April 24—New England Physical Therapy Society. See notice elsewhere on this page.

April 26—A Clinic on Pneumonia. See page 377.

April 27—New England Society of Psychiatry will meet at the Boston State Hospital, Dorchester Center, Mass., at 1 P.M.

April 30—The American Board of Dermatology and Syphilology Examinations for Certificates. See page 377.

May 3—Faulkner Hospital Clinical Meeting will be held at 5 P.M.

May 14, 15, 16, and 17—Thirtieth Annual Meeting of the National Tuberculosis Association. For details apply to the National Tuberculosis Association, 450 Seventh Avenue, New York City.

May 25, 27, 28, and 29—The American Association on Mental Deficiency. Details may be obtained from the Secretary Dr. Groves B. Smith, Godfrey, Illinois.

June 12—American Heart Association will meet at 9 30 A.M. at the Cleveland Hotel, Cleveland, Ohio.

July 24-31—The IVth International Congress of Radiology will be held in Zurich under the presidency of Professor H. R. Schnitz. General Secretary Dr. H. E. Walther, Gloriastrasse 14 Zurich.

September 3-6—American Public Health Association at Pasadena, California. Dr. J. D. Dunshee, Chairman, Local Committee on Arrangements.

September 4, 5, 6—International Union Against Tuberculosis. For information address the National Tuberculosis Association, 450 Seventh Avenue, New York City.

BOOK REVIEWS

Infections of the Hand A guide to the surgical treatment of acute and chronic suppurative process in the fingers hand, and forearm. By Allen B. Kanavel. Published by Lea & Febiger. Sixth edition. 552 Pages. Price \$6.00

In the sixth edition of this classic contribution on hand infections, Kanavel has not only revised the subject matter and added considerable new material, but has entirely rearranged its presentation. All expositions of methods of study, of anatomy, and of general principles have been assembled in Part I. Two new chapters on the function of the hand in relation to infections and on prophylactic treatment of injuries have been added. Parts II and III are clinical considerations of various phases of the subject and Part IV of complications, sequelae, and after treatment. To Part II on localized infections, such as felons, paronychia, carbuncles, minor space abscesses, has been added new material on indelible pencil injuries, milker's nodules, differential diagnosis of chancre, tularemia, sporotrichosis, coccidioides granuloma, blastomycosis, actinomycosis,

oriental boil and anthrax infections about metacarpophalangeal joints and human bites. All material on gangrenous infections has been assembled in one chapter, much of which is new. In Part IV, in addition to a thorough revision of former subject matter, is additional information on edema following infections and the use of splints after infections. In the fifth edition there were 196 illustrations. In the present edition there are 216. Some of the previous illustrations have been consolidated in single engravings, others have been omitted. Still others have been clarified and some new ones added from the hand of Mr. Tom Jones.

The physical make-up of the book is attractive with heavy boards and buckram, beautiful typography, and calendered paper which enhances the definition of the engravings.

Though other editions of this work, which has done more than any other contribution to place the subject on an intelligent and scientific basis, may be on the shelves of medical students, general practitioners, surgeons, and medical and hospital libraries, this sixth edition has been so thoroughly revised and augmented that it is necessary to discard the old and secure the new.

Manual of Urology By R. M. LeComte. Published by William Wood & Company. 1256 Pages. Price \$7.50

This manual of urology is well written, and contains the fundamentals of diseases of the genitourinary tract. It is short, concise, and well adapted for use by medical students, and nurses. Each disease is adequately described with its underlying pathology, symptomatology, differential diagnosis, course, prognosis and treatment. It is to be expected that in so brief a manual many fine points of diagnosis, treatment and pathology are necessarily omitted.

The author states that hypernephromata are the most common renal epithelial tumors in adults. It is the reviewer's opinion that renal cell adenocarcinoma are by far the most common renal neoplasms found in adults.

In classifying the causes of polyuria the author fails to mention infectious diseases as one of the common causes.

Diseases of the Nervous System By W. Russell Brain. Oxford Medical Publications, Oxford University Press, London. Humphrey Milford. 1933. 899 Pages.

There are many textbooks of neurology and some of the older ones are still of great value. Nothing has ever been written to compare with Oppenheim's two volumes, translated into English from the fifth edition in 1911. Even earlier is the splendid book by Gowers, giving his personal experiences as the result of many years practice in neurology. Both of these books are standard and all subsequent publications must necessarily be compared with them.

The book at hand for review is of a somewhat dif-

ferent character. It lacks the personal element found in the great neurological textbooks noted above. It does, however, give the neurologist the benefit of an excellent summary of the more recent additions to the subject. It is perhaps, a little technical for the average general practitioner, but, accurately written, one could hardly fail to obtain excellent information from a book of this type even though he had little experience with neurology. For the specialist the book does not add anything particularly new although it will serve as a convenient reference to the more recent literature, particularly on account of the extensive bibliography which is appended. Carefully produced, with a few well chosen illustrations this book is a distinct addition to the neurological field and both the author and the publisher deserve credit for embarking upon such an extensive adventure in these troublesome times.

Collected Papers of The Mayo Clinic and The Mayo Foundation Edited by Mrs Maud H Vellish Wilson and Richard M Hewitt. Volume XXIV 1932 Published by W B Saunders Company 1205 Pages. Price \$11.50

This the twenty-fourth consecutive volume of the *Collected Papers* contains ninety-nine full reprints of articles covering subjects of interest to the general surgeon, the internist and specialist. A tremendous field is covered by the list of titles in the literature enriched by the Rochester group, ranging from Rosenow's important work in poliomyelitis to the sage conclusions of Alvarez, a master physiologist and clinician.

A great mass of material is marshalled based on a wealth of clinical material. The reader can but note in these papers the same features that impress the visitor to the clinic itself: enthusiasm, sympathy and the highest standards of scientific investigation. The preëminent work of Adson in neurosurgery, of Desjardins in radiotherapy and Eusterman in gastroenterology are evident in these papers. The always interesting and worth while comments of the Senior Mayo on medicine as a science and as an art can never be extravagantly expressed.

Clinical experience, experimental research, critical judgment and thoroughness always characterize Mayo publications. They make this book a valuable addition each year to the library of the progressive physician.

The Surgical Clinics of North America December, 1933 Volume 13, Number 6 Pacific Coast Surgical Association Number and Index Number W B Saunders Company Philadelphia.

This issue is composed of contributions from thirty-seven members of the Pacific Coast Surgical Association. The unusually large number of clinics covers a wide range of subjects but consists chiefly in rather brief reports of interesting cases. The reviewer feels that those numbers that deal with fewer topics but discuss them more thoroughly are of greater practical value.

The Science of Human Reproduction By H M Parshley Published by W W Norton & Company, Inc, New York. 319 Pages Price \$3.50

Professor Parshley's book is a thoroughly satisfactory presentation of the facts, so far as they are known today, concerned with human reproduction. Its purpose is twofold — 'first to answer most of the questions that non professional students and intelligent laymen are likely to ask about the anatomy and physiology of human procreation and secondly, to provide the biological basis for a scientific attitude toward sex and its problems.

This purpose is admirably fulfilled. The author has selected the essential facts and has presented them clearly and with sufficient but not too great detail. The philosophical significance of conditions is kept constantly before the reader, and his interest is increased by the fact that not infrequently the author slips in a subtle bit of humor or some pertinent reference to conditions of modern civilization.

Although every part of this book is well done, the reviewer was especially impressed by the clarity of the discussion concerning those hormones that affect the sexual development of the individual and that influence the sexual cycle in women. The last two sections of the book 'Population and Eugenics' and 'The Biology of Sex Behavior,' are as sound a discussion of these phases of human reproduction as the reviewer has seen.

The book cannot be summarized; those who are interested in this most vital subject should read it for themselves.

Public Health Nursing in Industry By Violet H. Hodgson Published by The Macmillan Company 249 Pages Price \$1.75

The author states that 'the aim of this publication is to indicate the potential field of public health nursing in commerce, trade and industry.' Apparently this is another way of saying that it is intended to point out the possibilities of extending the field of employment for registered nurses. The book would seem to be well calculated to serve this purpose.

In connection with its object also certain biological and medical truths are presented in a way that deserves commendation. The following may be cited as an example:

Nutrition and food are not synonymous. Sufficient food is essential to nutrition but rarely is good nutrition dependent entirely upon food intake.

Important truths well stated platitudes relative to the value of health, unqualified assertions regarding conditions of disputed pathology and dogmatic prescriptions in the matter of the care of specified conditions are, however so interwoven as to make one wish that in connection with the arrangement of the subject matter and its presentation the

INTUSSUSCEPTION—THE RELATION OF THE CEREBRAL CORTEX TO INTESTINAL MOTILITY IN THE MONKEY*

BY JAMES W. WATTS, M.D.,† AND JOHN F. FULTON, M.D.‡

I. INTRODUCTION

THE unexpected appearance of intussusception as a cause of death in a group of monkeys which had been subjected to bilateral removal of the premotor areas of the brain^{10, 16, 17, 22} has necessitated examination of the etiology of intussusception, and it has led to a consideration of the influence exerted by the cerebral cortex on the motility of the gut. During the past three years careful autopsies have been performed in this laboratory on nearly three hundred monkeys and anthropoid apes of various species, almost all of which had been subjected at one time or another to surgical procedures on the brain or spinal cord (with intraperitoneal anesthesia), but intussusception had been observed in only three instances (see below, Autopsy V) in unoperated animals which had died obscurely, presumably from intestinal infestation.

In a recent investigation^{16, 22} upon the functions of the premotor area some ten monkeys have had portions of their frontal lobes, including the premotor areas, removed from both hemispheres. Three of them died soon after the second premotor area was removed (see below, Autopsies I, II, III) with signs of intestinal obstruction, and at autopsy intussusceptions were disclosed. In several other instances, following premotor lesions, intussusceptions have been observed without obstruction. It is conceivable, though scarcely probable that these occurrences were purely fortuitous, but they clearly merited close examination and the present paper records the results of our study.

The possible rôle played by the nervous system in the production of intussusception has often been discussed, but before taking up the question it is essential first to consider the mode of production of intussusception, i.e., the mechanical problem. The clearest description to be found in English literature, is probably that of Fraser¹⁵, who wrote as follows:

"The mechanical process which results in the production of an intussusception is comparative-

ly simple. It would seem that an irregularity in the conduction of the peristaltic wave is the underlying cause. A ring of contraction develops in a segment of the bowel for some reason this is not transmitted, and its persistence at one point results in the invagination of the active portion into the lumen of the passive segment lying in continuity with it. The invagination of the advancing bowel results in a stimulation of the receiving portion, and this stage is actually the most critical of the whole process of intussusception, the contraction of the receiving bowel will have one of two possible effects—it will either expel the invaginating segment, in which case the danger has passed with no more symptoms than a passing colic, or, if its contraction has been longer delayed, it will grasp the entering segment, and actually force it along its invaginating course.

"While we may imagine the mechanical error to be somewhat on the lines described, there is difficulty in discovering the source of the original local peristalsis. It is probable that several factors are at fault.

"Irritation of the mucous membrane has an influence on the production of the error. There is a structural peculiarity of the intestine which predisposes to the disease. It is possible that an error in the arrangement of the splanchnic nervous system may influence the incidence of the disease. There are cases of intussusception in which the inversion of a diverticulum, the presence of a polypus or of a swollen hypertrophied Peyer's patch is the original stimulating factor of the peristalsis."

Fraser¹⁵ mentions the possibility of an error in arrangement of the splanchnic nervous system being a factor in intussusception, and while the suggestion is frequently seen no experimental study of the problem appears to have been made, and certainly there is no record in the literature of an intussusception produced by peripheral stimulation of any of the nerves to the gut.

Clinically intussusception is one of the commonest and most dangerous causes of intestinal obstruction, but it is almost entirely confined to children under five years of age (Homans¹²). Perrin and Lindsay^{3, 4} observed that 69 per cent in their series of intussusceptions were in infants under one year of age. Intussusception

A LATE NOTICE

PHI DELTA EPSILON FRATERNITY

On Monday, April 23, at 8 P.M., the Phi Delta Epsilon Fraternity of Boston University School of Medicine will hold another of its open meetings at the Evans Memorial Hospital Auditorium, 80 East Concord Street, Boston

Dr Frank M Lahey, of the Lahey Clinic, will speak on "Thyroid Disease, Its Diagnosis and Management" and Dr Lewis M Hurxthal, of the Lahey Clinic, will talk on "Myxedema, Hypometabolism, and Blood Cholesterol" Dr Allan Winter Rowe, Director of Clinical Research of the Evans Memorial Hospital, will lead the discussion.

of the intestine at the site of the obstruction and below it. The intestine for 3 or 4 cm above the obstruction was definitely constricted, that below, dilated.

The discoloration of the intestine at the site of the obstruction indicated that the intussusception was present before death. That it was recent, was shown by the relatively slight disturbance of blood supply and by the presence of a constricted gut above the obstruction. Of course, it is possible that reduction of the intussusception might have occurred spontaneously had the animal lived.

Autopsy III (Corpus callosum IV Intussusception XII) Mature male green monkey (Cercopithecus sabaeus aethiops) Weight 3200 gm Intussusception found in animal following removal of the left motor and premotor area

Previous operations—February 3, 1933 The left motor and premotor areas were extirpated.
March 9, 1933 The corpus callosum was transected.

March 22, 1933 A total transection of the spinal cord was made at the level of the 10th thoracic segment. Following the last operation, the general condition of the animal grew worse. A pressure sore developed over the left hip, so it was sacrificed March 31 1933.

Autopsy findings (March 31 1933)—The stomach was dilated and the intestines were atonic and somewhat distended. In the small intestine 40 cm below the pylorus was an intussusception 3 cm long. The loops of gut below the obstruction were definitely darker in color than the loops above it. The lower part of the intussusciplens was also discolored. The blood vessels in the wall of the intestine above and below the obstruction were very prominent, and especially below there was a diffusion of blood into the mucosa radiating out from the blood vessels.

No inflammatory changes were present in the gastrointestinal tract of the preceding cases (Autopsies I, II and III) nor was there any local abnormality which might be pointed to as the possible cause. There was a disturbance of the blood supply to the intestine below the site of obstruction in all three animals and it is clear that the obstruction was a contributing, and probably the chief cause of death. The following case (Autopsy IV) is that of an animal which had a stubborn diarrhea before it was operated on and was subjected to an experiment in carbohydrate metabolism subsequently.

Autopsy IV (Area 6 Series, No XX) Immature female Macaca mulatta Weight 1800 gm Intussusception found after operation on area 6 in animal which previously had diarrhea

Previous operations This young macaque had a stubborn diarrhea which failed to respond to treatment before an experiment was performed. On March 8 1933 a small area, 2 mm. in diameter was excised from the anterior end of the superior precentral sulcus of the left premotor area.

March 20, 1933 The animal was isolated, given water but no food, and injected daily with phloridzin for an experiment in carbohydrate metabolism. On March 22, a reddish fleshy mass was observed protruding from the rectum.

Autopsy findings (March 22, 1933)—The animal was sacrificed under ether anesthesia. When the abdomen was opened, an intussusception of the descending colon was found. The intussusception was composed entirely of descending colon including the mass protruding from the rectum. The intussusciplens was largely rectum, though the upper 1 cm of it may have been colon. The mucosa of the small and large intestines was slightly pinker and more injected than normal.

Fortunately, during the year, two unoperated animals were found to have intussusception at autopsy. If these had not occurred it might have been a temptation to neglect other factors concerned in the etiology of intussusception and to overstress the influence of the central nervous system. One animal (Autopsy V) presented evidence of a generalized infectious process and marked inflammatory changes in the gastrointestinal tract. No predisposing cause of the intussusceptions could be found in the other animal (Autopsy VI).

Autopsy V (Normal green, III) Cercopithecus sabaeus aethiops Weight 3000 gm Intussusception in unoperated animal that died of a generalized acute toxic process

Past history This was an unoperated animal which had recently arrived in the laboratory. No detailed observations had been made but it was noted that the monkey was not so active and alert as its fellows. The morning of June 17 it was found dead in its cage.

Autopsy findings (June 17 1933)—The great omentum was very hemorrhagic in appearance especially near the blood vessels. The parietal peritoneum contained many diffusely scattered punctate hemorrhages. The visceral peritoneum was also the site of punctate hemorrhages. The intestinal wall was a pea soup green having been discolored by the fecal contents. Considerable gas was present in the intestines.

Further examination disclosed 2 intussusceptions near the junction of the middle and upper third of the small intestine. The more cephalad intussusception was 5 mm in length and the more caudal was 20 mm long. Possibly the discoloration below the second intussusception was greater than that above but the difference was very slight.

The fecal contents had the appearance and consistency of pea soup. The intestinal mucosa was swollen velvety and assumed the color of the feces. A few scattered fresh hemorrhages were noted in the mucosa.

The spleen was swollen and firm to palpation. On cut section it had a septic appearance. The kidneys were swollen and flabby. Pus was present in the left kidney pelvis.

Autopsy VI (Normal green, V) Cercopithecus sabaeus aethiops Weight 2575 gms Intussusception in unoperated animal

Past history This was an immature male green monkey, which had arrived in the Laboratory ten days previously. During the two or three days preceding death it had appeared sick, did not jump about the cage as usual when food and water were placed before it by

occurs twice as frequently in boys as in girls, and is more common in well nourished than in malnourished children (Ochsner³⁰). It is extremely rare in adults, in whom, however, it may be initiated by the drag of a pedunculated benign or malignant tumor (Homans¹⁰).

II PROTOCOLS OF AUTOPSIES

Soon after beginning a study of the effects of localized lesions in the hypothalamus on the heart and the gastrointestinal tract it became obvious that an accurate knowledge of the normal variations in the gastrointestinal tract of primates must be obtained (Watts and Fulton⁴⁰). For this purpose one of us (J. W. W.) performed complete autopsies on all animals that were sacrificed or died during the year, some 80 in number, devoting special attention to the gastrointestinal tract. It was while making these routine examinations that interest was aroused in the problem through the discovery of intussusception with obstruction in several monkeys from which the premotor area had been previously extirpated.

These instances may be described briefly as follows:

Autopsy I (Frontal IV) Adult male Java monkey (Macaca irus) Following cortical extirpation, vomiting and prostration developed. Intussusception found at autopsy.

Previous Operations—July 5, 1932 Both frontal lobes including most of the premotor areas were radically ablated.

October 10, 1932 The remaining cortical tissue anterior to the central sulcus was extirpated from the left hemisphere. There were no gastrointestinal symptoms after either operation.

November 17, 1932 The remaining cortical tissue anterior to the right central sulcus was extirpated.

Following the last operation the animal was unable to sit or stand alone, and it had to be fed. Its general condition and appetite were good until the sixth day after operation when it suddenly became prostrated and vomited. The vomiting continued for several hours and was associated with coarse lateral nystagmus. The operative incision was well approximated, there was no evidence of infection, or of increased intracranial pressure. As it was evident that the animal could not live through the night it was sacrificed under dial anesthesia on the sixth day after operation.

Autopsy findings (November 23, 1932)—Upon opening the abdomen an intussusception 8 cm long was discovered in the small intestine 42 cm below the pylorus (Fig 1). The mesentery had been dragged into the intussusciplens with the intussusceptum. There was a disturbance of blood supply to the intestine indicated by the marked discoloration of the intestine at the site of and below the obstruction.

The intussusception had produced an intestinal

obstruction with an interference of the blood supply to the bowel. This was adequate cause for the prostration and vomiting which were observed. The next two cases are similar, but case 3 is complicated by the presence of a spinal transection.

FIG 1 (Autopsy I) A drawing of the obstructive intussusception disclosed in Autopsy I as it appeared externally (above) and after dissection (below)

Autopsy II (Area 6 Series, No 1) Adult Macaca mulatta Weight 3800 gms Intussusception found in animal following bilateral extirpation of motor and premotor areas of the cortex.

Previous Operations—January 5, 1933 After faradic stimulation of areas 4 and 6 of the left hemisphere, area 4 was extirpated.

January 26, 1933 The left bone flap was reelevated, area 6 was stimulated and then extirpated.

February 9, 1933 Through a right sided bone flap, the motor and premotor areas were stimulated, then excised. As usual after removal of the second motor and premotor areas, there was an absence of voluntary power in the contralateral and ipsilateral extremities.

The condition of the animal was good for several days after operation. Although the appetite was good, and it was carefully fed by hand, the animal lost weight. On February 15, it refused food and the following morning was found dead in its cage. No signs of an acute nature such as were observed in the previous case (Autopsy I) were noted in this animal. There was no vomitus in the mouth or on the face.

Autopsy findings (February 16, 1933)—An intussusception was found in the lower ileum 10 cm from the cecum. The intussusception measured 2 cm, the mesentery had been pulled in with the intussusceptum, and there was some discoloration

in cephalad segments reached the contracted segment but did not pass it

10 30 A.M. With the coil at 10 cm Point 2 was stimulated for 1 minute

30" after stimulation was started, a bud was seen forming at the lower end of the cecum

50" the bud was growing in size This was associated with a slight general contraction of the entire cecum

60" a narrow band of contraction was seen in the small intestine and was not transmitted At this time the evagination on the cecum measured 10 mm long and 8 mm in diameter

10 34 A.M. The cecum had been slowly contracting and relaxing since the cortex was stimulated at 10 30, a cycle lasting about 2 minutes

10 35 A.M. All was quiet

10 36 A.M. With the coil at 10 cm, Point 3 was stimulated faradically 3 minutes

20" after stimulation was started, a band of contraction made its appearance 15 mm from the lower end of the cecum

30" contraction of the cecum continued

50" a second constricting band appeared on the cecum proximal to the first

70" a narrow ring-like band was noted circumscribing the small intestine, which was not transmitted

90" a peristaltic wave arising above passed caudally, broke against the narrow contracted segment The constriction remained localized in its original segment of gut Relaxation was occurring in the cecum

120" the cecum was again in the process of contraction and a ring-like band was forming in another segment of small intestine which did not move down the gut

180" all motility had ceased.

10 50 A.M. The intestines were quiet

11 05 A.M. The left vagus nerve was exposed in the neck

11 15 A.M. The left vagus nerve was stimulated with the coil at 10 cm The heart ceased 1 to 2 seconds, resumed beating, attained a rate of 60 and while still being stimulated resumed its usual rate The pyloric region of the stomach contracted, but no peristalsis or segmental contractions occurred in the intestines

11 18 A.M. Spontaneously, a bud was seen forming on the cecum When the vagus nerve was stimulated, the cecum relaxed When the stimulus was removed the cecum again contracted

11 22 A.M. Spontaneously, a bud appeared on the cecum and a ring-like band of contraction was seen forming in the small intestine With the coil at 10 cm, Point 6 was stimulated This was followed by acceleration in the movement in both cecum and small intestine

11 45 A.M. The right cerebral hemisphere was exposed At this time there was neither peristal-

sis nor other signs of activity in the gut Short faradic stimuli applied to Point 5 and other points on the motor area of the right hemisphere excited normal responses in the extremities, but no effect on the intestines

11 50 A.M. Point 7 on the right hemisphere was stimulated 1 minute with the coil at 11 cm

30" after stimulation was started the tip of the cecum was evaginated and a narrow ring-like band circumscribed the small intestine, which was not transmitted

11 55 A.M. Point 7 was again stimulated with similar results

12 00 Noon With the coil at 11 cm, Point 6 was stimulated 1 minute Activity was observed in the cecum after 50" but none in the small intestine

12 05 P.M. Point 1 was stimulated 2 minutes with the coil at 11 cm

20" after application of the electrode, the lower end of the cecum contracted vigorously

30" a strong ring like band of contraction appeared in the small intestine but was not transmitted

60" the cecum was beginning to relax.

90" the cecum had relaxed, but the ring of contraction was still present in the small intestine

12 10 P.M. Point 3 was again faradized with similar responses to those elicited at 12 05 P.M.

12 24 P.M. 0.4 cc of ephedrine was given intramuscularly

12 29 P.M. The heart sounds were strong and rate unchanged The intestines appeared somewhat dilated and flabby, and slightly paler

12 30 P.M. The intestines and brain were definitely paler than before With the coil at 10 cm, Point 1 was stimulated 1 minute Within a few seconds of the beginning of stimulation, the lower part of the cecum was contracting vigorously A narrow ring of constriction appeared in the small intestine The ring circumscribing the intestine widened into a band It reached 10 mm, then 15 mm It was not transmitted Peristaltic waves arising in cephalad segments broke against the contracted segment, but were unable to pass or to alter the band of contraction One peristaltic wave more forceful than the rest reached the ring of contraction, and simultaneously invagination of the active portion of the gut into the passive segment lying in continuity with it occurred An intussusception was present which measured 15 mm in length

12 36 P.M. The intussusception was still present and unaltered in appearance

Stimulation of the cerebral cortex, particularly area 6 (Fig 2), excited activity of an abnormal type in the small intestine A ring of contraction developed in a segment of bowel and for some reason was not transmitted Its per-

an attendant It was found dead in its cage the morning of July 1, 1933

Autopsy findings (July 1, 1933)—When the peritoneal cavity was opened, an excessive amount of free fluid was present. There was an intussusception of the ileum through the ileocecal valve into the cecum. The intussusciptens measured 12 cm. In the ascending colon was an intussusception measuring 7 cm with marked discoloration of the involved segments as well as the bowel below the obstruction. A third intussusception was present in the descending colon, 8 cm long, likewise with marked circulatory disturbances at the site and below the obstruction. The mucosa of the rectum was normal in color and appearance. There was no evidence of a generalized enteritis or colitis.

III CORTICAL STIMULATION

Though suggestive the first three autopsies described above would in themselves allow no definite conclusions, and we were therefore led to investigate the effect of cortical stimulation on gastrointestinal motility. That cortical stimulation influences peristalsis has been known since the classical experiments of Bochefontaine⁸ in 1876. He found that stimulation of the region of the sigmoid gyrus of the dog usually diminished or completely inhibited rhythmic contractions of the stomach. However, the inhibition was often immediately preceded by a strong peristaltic contraction of the entire pyloric region. Sometimes peristalsis was excited in various segments of intestine, now in the duodenum, again in the ileum.

The subjects of most of our experiments were monkeys having previous intracranial operations, which were to be sacrificed to obtain the brain for anatomical studies. This accounts for some of the apparently bizarre procedures antedating the present experiments. Such animals, however, were often of more value than a normal animal in analyzing the results, since they allowed more precise localization of excitable areas.

Methods—After the cortex had been exposed the peritoneal cavity was opened. The cortex was kept moist with warm, physiological saline. In the earlier experiments the intestines were kept moist by sprinkling them with saline, but in later experiments, the animal was placed in a saline bath at 38° C, so that the intestines were largely immersed in saline, sometimes floating somewhat, depending on their gaseous content. The temperature of the fluid was kept constant by means of an electric light bulb.

In Experiments 1, 7, 8, 11, 12, and 13, the cortex was stimulated with a unipolar electrode with the indifferent electrode in the rectum. To avoid the possibility of stimulation from the indifferent electrode or the criticism its use might cause, in Experiments 2, 3, 4, 5, 6, 9, and 10, the cortex was stimulated by means of a bipolar electrode. Using a Harvard induc-

torium, the best results were usually obtained with the coil at 9 or 10 cm. The points most frequently used for stimulation in the various experiments are indicated diagrammatically by arabic numerals in figure 2.

FIG 2 Diagram of the cerebral hemisphere of a monkey showing the points stimulated. This applies to all experiments (1 to 13).

Experiment 1 (Corpus Callosum V Intussusception I) Mature *Macaca mulatta* Weight 3450 gm. Intussusception in small intestine and vigorous activity in cecum produced by faradic stimulation of premotor area.

Previous operations—February 17, 1933, the main trunk of the anterior cerebral artery was ligated at the genu of the corpus callosum, and the callosum sectioned. No impairment of motor function followed. The animal had diarrhea which failed to respond to treatment.

Observations upon intestine—March 24, 1933. Under ether anesthesia the left bone flap was reelevated and the peritoneal cavity opened. The blood vessels in the intestinal walls were considerably injected. Observations from 9 40 to 10 00 A.M. showed very slight peristaltic movements of the small intestines, but none in the stomach or large intestine. Throughout the experiment the intestines were kept moist by sprinkling them with normal saline at 38° C. 10 20 A.M. With the coil at 10 cm. Point 1 (Fig 2) was stimulated for 1 minute with a unipolar electrode with the indifferent electrode in the rectum.

20" after the application of the electrode to the cortex the cecum began to contract. A bud-like evagination formed on the lower end of the cecum. As contraction of the musculature continued, the bud constricted at the base 1 cm. from the tip.

40" after application of the electrode to the cortex, a narrow ring-like band of contraction was seen circumscribing the small intestine. The band gradually widened from 1 to 2 mm and finally to 10 mm. The band remained contracted and was not transmitted down the gastrointestinal tract. A peristaltic wave arising

through it. The activity lasted 2 minutes after the stimulus ceased and gradually relaxed. Point 4 was stimulated 6 different times, each time causing a striking "peristaltic rush." When the electrodes were moved a few mm distant from Point 4, stimulation failed to excite peristalsis.

Once during the experiment, the anesthesia became too light. When ether was administered, the animal struggled and a "peristaltic rush" occurred in the large intestine similar to that produced by stimulation.

Experiment 4 (Bouton V Intussusception XII). Immature female Macaca mulatta. Weight 2000 gm. Rhythmic contractions of the cecum initiated by faradic stimulation of area 6.

Previous operations. March 27, 1933, the left premotor area was extirpated with a resulting right hemiparesis.

Observations upon intestines—March 30, 1933. The right motor and premotor areas were exposed and the abdomen was opened under ether anesthesia. The small intestine was collapsed. The large intestine contained a small amount of gas and fecal material. No peristaltic activity was visible in the intestines. The animal was placed in a bath of normal saline at 38° C so that the intestines were partly submerged and partly floating. The change in environment did not result in increased motility of the intestines.

Stimulation of Point 4 faradically with a bipolar electrode 1 minute elicited contraction of the cecum. After a latent period of 30 seconds a bud-like process appeared on the end of the cecum. When Point 4 was stimulated 6 minutes later, the latent period was only 15 seconds and rhythmic contractions were set up at the rate of 1 cycle per minute, i.e. contraction occurred producing a bud and relaxation followed within a minute. Similar activity in the cecum was elicited by stimulation of Point 3 (Fig. 2).

At no time was motility observed in the small intestine or colon. No response could be obtained in the cecum 20 minutes after the first cortical stimulation. Likewise, stimulation of the motor area with twice the usual strength failed to yield movement of the extremities at this time.

Experiments 2, 3 and 4 confirm the results given in detail in Experiment 1. Stimulation of area 6 excited rhythmic activity in the cecum of all 3 animals. In Experiments 2 and 3, ring-like bands of contraction which were not transmitted appeared in the small intestine under the influence of premotor stimulation. In Experiment 3 a transient intussusception was observed, and a "peristaltic rush" was produced in the large intestine.

It was observed that the responses of the gas-

trointestinal tract to cortical and vagus stimulation were dissimilar. When the vagus nerve was stimulated in the neck, contraction of the pyloric region of the stomach occurred, followed by contraction of the body of the stomach. When the cortex was stimulated, the stomach did not appear to be affected, but definite activity resulted in the intestines. The observations suggested selected action on specific fibers or that some pathway other than the vagus might contain motor fibers to the gastrointestinal tract. As one method of attacking the problem several animals were vagotomized and the cortex stimulated. The following experiments (5, 6, and 7) show the results as well as some of the difficulties of interpretation.

Experiment 5 (Hypothalamus VIII Intussusception XVI). Mature male Macaca mulatta. Weight 6300 gm. Activity of cecum and small intestine elicited by faradic stimulation of the premotor area. Slight motility excited in small intestine by cortical stimulation after bilateral vagotomy.

Previous operation. A small lesion was made in the hypothalamus by the transcallosal route. Except for a rapid gain in weight following operation, the animal was normal in every respect.

Observations upon intestines—June 9, 1933. The experiment was performed under ether anesthesia. A right osteoplastic flap was elevated and both vagus nerves were exposed in the neck. Immediately after the peritoneal cavity was opened the animal was placed in a bath of normal saline at 38° C. The small intestine contained a little gas, but most of the intestine lay with the walls in contact, the cecum was relaxed, but the colon was constricted. No peristalsis or segmentation was seen. A spontaneous contraction of the cecum was observed before electrical stimulation was begun. A definite bud-like evagination appeared and relaxed.

Faradic stimulation of Point 1 (Fig. 2) initiated vigorous rhythmic contractions of the cecum associated with mild peristaltic movements of the small intestine. Activity in the cecum continued 3 minutes after the stimulus ceased. On one occasion during the experiment the depth of anesthesia became very light. When ether was administered the animal struggled and during the struggles vigorous motility in the cecum of a rhythmic character appeared.

Cutting the left vagus nerve in the neck appeared to cause pain, and the cecum contracted strongly. While the cecum was in a state of moderate contraction the left vagus nerve was sectioned. Relaxation and dilatation of the cecum and colon appeared immediately, but no change was noted in the small intestine. Considerable respiratory difficulty ensued.

Point 1 stimulation of which excited activity

sistence at one point, aided by peristaltic waves from cephalad segments resulted in invagination of the active portion into the lumen of the passive segment lying in continuity with it. The invagination of the advancing bowel resulted in stimulation of the receiving portion which grasped the entering segment. The administration of adrenalin intramuscularly did not interfere with the effects of cortical stimulation. After the intussusception had persisted 10 minutes, the abdomen was closed and dial was given intraperitoneally. When examined 2 hours later the intussusception had disappeared.

No less striking in this experiment was the rhythmic activity excited in the cecum by cortical stimulation. After activity had been initiated the tip of the cecum often continued to contract and relax for several minutes after stimulation had ceased.

Short stimuli such as give good motor responses of the digits (2-5 seconds) did not excite movements of the intestine. When a 1 minute stimulus was applied, usually 15 to 30 seconds elapsed after stimulation was begun before activity was noted in the intestines. Working against a static background, no inhibitory effects of cortical stimulation were observed.

A detailed protocol of each experiment would require excessive space. However, it would appear advisable to give a summary of each experiment in which the cortex was stimulated because many differences are presented which will be referred to in the discussion.

Experiment 2 (Intussusception IX Area 6, Series XXV) Immature female Macaca mulatta. Weight 1700 gm. Excitation of activity in cecum and small intestine by stimulation of area 6. Using bipolar electrode under ether anesthesia.

Previous operations. There was a paralysis of the left lower extremity and a sensory level in the left mid-thoracic region as a result of a left hemisection of the spinal cord made at 10 00 A.M. March 24, 1933.

Observations upon intestine—March 24, 1933. Under ether anesthesia the right motor and premotor areas were exposed and the abdomen was opened. Most of the small intestine was atonic and collapsed, and the large intestine was filled with gas. Blood vessels in the intestinal walls were prominent. No intestinal motility was observed.

Faradic stimulation of the motor and premotor areas 5 to 10 seconds caused the usual responses in the extremities. This was repeated several times but no changes in the appearance or motility of the intestines were observed.

Stimuli lasting 2 to 4 minutes applied to the premotor area (Points 1 and 2, Fig. 1) initiated great activity in the cecum and small intestine. Rhythmic contractions of the tip of the cecum

were set up at the rate of 2 or 3 a minute, often continuing after the stimulus was removed. A ring-like band of contraction in the small intestine was often produced. Usually a narrow band of contraction appeared, relaxed, contracted again, but was not transmitted. Occasionally during stimulation, a peristaltic wave was seen in the small intestine passing caudally 2 to 3 cm, then in the opposite direction in the same piece of gut.

The latent period from the application of the stimulus to the appearance of intestinal activity, was usually as great as 60 seconds during the first part of the experiment, and often as little as 10 seconds during the latter part.

Stimulation of Point 2 produced the greatest activity. Often no increase in motility was obtained from nearby points.

Experiment 3 (Area 6, Series XXII Intussusception X) Immature male Macaca mulatta. Weight 2300 gm. Production of peristalsis and a transient intussusception in the small intestine, and a "peristaltic rush" in the large intestine by stimulation of area 6.

Previous treatment. Food was withheld from the animal four days and phloridzin injected daily for an experiment in carbohydrate metabolism. At the beginning of the metabolism experiment the animal was normal except for a diarrhea which had been present several days.

Observations upon intestine—March 29, 1933. Under ether anesthesia the left cerebral cortex was exposed and the abdominal cavity opened. The liver presented a typically diabetic appearance. The small intestine was completely collapsed with the walls in contact and longitudinal striations plainly visible. The transverse colon had a beaded appearance, but there were no bands of constriction. No activity was observed in the gastrointestinal tract. The intestines were floated in a bath of normal saline at 38° C. Within a few seconds peristalsis appeared in many loops of small intestine, but ceased in 5 minutes.

Stimulation of Point 1 (Fig. 2) with a bipolar electrode excited ring-like bands of contraction in the small intestine which were not transmitted. After this point had been stimulated faradically several times for 1 minute each, an intussusception made its appearance. Ten minutes after it was first observed, the intussusception spontaneously released itself.

One minute faradic stimulation of Point 4 initiated a vigorous "peristaltic rush" in the descending colon. The wave of contraction began 15 seconds after the application of the electrode. This was transmitted rapidly through 16 to 18 cm, the colon contracting down like a cord and straightening out like a coiled rubber tube when a stream of water is passed

animal (protocol not presented) with generalized peritonitis failed to give the usual intestinal response on cortical stimulation. Using dial as an anesthetic, cortical stimulation failed to excite intestinal activity. This is well demonstrated in Experiment 8 and confirmed by the use of dial in the latter part of Experiment 10. Whether or not it has any significance here, it may be noted that Bucy⁹ was unable to elicit movements of the ipsilateral extremities under this anesthetic, though he could obtain them under ether.

Experiment 8 (Intussusception III) Medium sized Macaca mulatta. Weight 2250 gm. Under dial anesthesia, cortical stimulation had no influence on intestinal motility.

Previous operations. March 8, 1933, under dial anesthesia, Dr. Paul C. Bucy, who was studying the effects of cortical stimulation on ipsilateral movements of the extremities, had repeatedly stimulated area 6. No movements of the ipsilateral extremities could be elicited, but the contralateral extremities responded essentially as under ether anesthesia.

Observations upon intestines.—March 8, 1933. The peritoneal cavity was opened at the conclusion of the experiment noted above. The stage of anesthesia was very light. The small and large intestines were atonic or relaxed, and the blood vessels were injected. No peristalsis was observed.

Points 1, 2, 3, 4 and others were stimulated with a bipolar electrode, gradually increasing the strength to well above that usually employed. No response was seen in the intestines and their appearance was not altered.

Application of the electrode to the peritoneal surface of the small intestine excited a ring-like band of contraction at the site of the stimulus. The contraction appeared after 5 to 10 seconds of stimulation and was not transmitted.

Stimulation of the left vagus nerve in the neck 15 seconds gave the usual cardiac response and a vigorous contraction of the pyloric region of the stomach, but no alteration in the intestines. When the nerve was stimulated 45 seconds similar results occurred and in addition very gentle intestinal peristalsis.

In most of our earlier experiments, the chief aim was to determine whether or not cortical stimulation had any influence on gastrointestinal motility. Since the autopsies suggested a relationship with area 6, this region was usually chosen first for stimulation. After this fact had been established, other areas within the operative field were stimulated. Experiments 9 and 10 demonstrate that intestinal motility can be produced by faradic stimulation of the postcentral gyrus and the frontal region anterior to area 6. Attention is called to the

fact that stimulation of the postcentral gyrus within 1 or 2 mm. of the central sulcus excited intestinal activity, but did not excite movements in the extremities such as would have been the case had there been a spread of current. Also as control, after stimulating a point on the cortex, the electrode was transferred to the falx cerebri adjacent to it. When there was any indication of a spread of current, the strength of the current was reduced and new observations made. Experiment 10 is considered significant as suggesting a possible influence of the frontal and postcentral areas upon intestinal movements, because area 6 had been ablated at a previous operation.

Experiment 9 (Corpus callosum IX Intussusception XV) Immature Macaca mulatta. Weight 2300 gm. Motility of cecum initiated by faradic stimulation of the premotor area and the postcentral gyrus.

Previous operations.—On May 19, 1932, a left bone flap was elevated, the anterior cerebral artery ligated at the genu of the corpus callosum, and the corpus callosum sectioned. Three days later after stimulation of areas 4 and 6 on the right side these were extirpated. The animal's condition remained good, and during the following week it recovered considerable use of the left arm and leg so that locomotion was quite good.

Observations upon intestines.—May 31, 1933. Under ether anesthesia, the left bone flap was reelevated and the abdomen opened. No motility was observed in the small intestine or the colon. The cecum was seen to contract slowly once over a period of five minutes. The intestines were floated in normal saline 38° C without excitation of motility.

Faradic stimulation of Point 1 (Fig. 2) with a bipolar electrode for one minute initiated a vigorous contraction of the cecum. The contraction started 20 seconds after the electrode was applied to the cortex. Rhythmic contractions of the cecum continued after the stimulus ceased, a cycle of contraction and relaxation lasting about one minute.

Likewise stimulation of Point 7 on the postcentral gyrus excited rhythmic contractions of the cecum. Spread of current was excluded by applying the electrode to the falx cerebri near Points 1 and 7 without effect.

No motility was observed in the small intestine or the colon. No further responses could be obtained in the cecum 20 minutes after the first cortical stimulus. However, faradic stimulation of the left vagus nerve was still effective, causing slowing of the heart, contraction of the pyloric region of the stomach, but no effect on the intestines. A second vagal stimulus appeared to excite activity in the cecum, and a

ity in the cecum and small intestine before vagotomy, was again stimulated faradically. After a latent period of 30 seconds, a ring-like band of contraction made its appearance in the small intestine. Five minutes later, Point 1 was again stimulated, and this time after 90 seconds' stimulation, a similar band of contraction appeared in the small intestine. The cecum responded in no way.

The animal died a respiratory death. No peristalsis or segmentation was present during the respiratory difficulties just preceding death. However, 2 minutes after the pulse and respiration ceased, vigorous activity began in the cecum, and active peristalsis and forceful rhythmic segmentation were observed in the small intestine. This extreme activity lasted 3 to 4 minutes and then ceased rather abruptly.

Experiment 6 (Pilocarpine XIII Intussusception XIV) Immature female Cercopithecus sabaeus. Weight 2500 gm. Initiation of peristaltic activity by stimulation of area 6 after bilateral vagotomy.

Previous operations. December 8, 1932, a complete subdiaphragmatic vagotomy was done on the left side. February 17, 1933, the right vagus nerve was sectioned in the neck, sparing the laryngeal branch.

Observations upon intestines—March 28, 1933. Both motor and both premotor areas were exposed using ether anesthesia. The left vagus nerve was dissected free in the neck. Both cut ends of the previously sectioned right vagus were identified. The distal end of the right vagus was adherent to the recurrent laryngeal nerve.

The animal was placed in a bath of normal saline at 38° C when the peritoneal cavity was opened. The small intestines were distended with gas. Several slowly contracting isolated bands were noted and one peristaltic wave was seen moving down the gut. The cecum was dilated and the colon was constricted, both were quiet.

Stimulation of Point 1 and Point 2 of the right hemisphere exerted no response in the gastrointestinal tract. When the peripheral stump of the right vagus nerve was stimulated it produced definite activity in the small intestine. One minute stimulation of Point 1 of the left hemisphere caused ring-like bands of contraction in the small intestine within 15 seconds after the application of the electrodes. The segmental contractions were maintained 3 or 4 minutes. After section of the left vagus nerve faradization of the peripheral end produced the characteristic cardiac and respiratory responses, but no effect on the gastrointestinal tract.

After carefully destroying all nerve fibers in and near the carotid sheath on both sides of the neck including any part of the vagi that might

possibly have been left behind, Point 1 on area 6 of the left hemisphere was again stimulated. Again intestinal activity was increased, though the response was definitely less than those obtained in the early part of the experiment.

Experiment 7 (Intussusception II Pilocarpine XVIII) Immature female Macaca mulatta. Weight 1700 gm. After previous complete subdiaphragmatic vagotomy, no response of intestinal tract followed cortical stimulation.

Previous operations. On February 17, 1933, a complete bilateral subdiaphragmatic vagotomy was performed.

Observations upon intestines—March 7, 1933. Under ether anesthesia the left cerebral cortex was exposed. When the peritoneal cavity was opened, considerable activity was present in the gastrointestinal tract. A ring-like band of contraction 3-4 mm wide was being transmitted down the small intestine at the rate of a normal peristaltic wave. The band of contraction was sharply delimited and very pale due to the fact that blood was being forced out by the tightly contracted intestinal musculature. In addition, the usual type of peristaltic waves was observed in the small intestine. The cecum was under going rhythmic contractions. In the systolic phase, the evagination formed on the end of the cecum resembled a vermiform appendix. This type of activity continued uninterrupted during the 20 minutes of observation.

With the unipolar electrode and the indifferent electrode in the rectum, various points on the cortex were stimulated. Normal motor responses of the arm and leg were obtained from areas 4 and 6 (Fig 2). However, no effect was observed on motility of the intestinal tract even when the strength and duration of cortical stimulation were more than doubled. The intestinal movements were neither accelerated nor inhibited from any part of the cortex.

After first stimulating the premotor area and obtaining good responses in the intestinal tract, a bilateral vagotomy was done in the neck. Following vagotomy, cortical stimulation appeared to cause an increase in motility, though definitely less than before vagotomy (Experiments 5 and 6). The latent period was unusually long before the response was noted. One naturally asks if all the vagus fibers in both sides of the neck were destroyed. It is believed that all fibers in both sides of the neck were destroyed. In one case Bechterew and Mislowski⁶ observed contraction of the small intestine on stimulating the last two thoracic and the first lumbar nerves.

However, cortical stimulation in one animal (Experiment 7), which previously had a complete bilateral subdiaphragmatic vagotomy, failed to elicit responses in the intestines. One

half to three hours. The abdomen was untouched.

Autopsy. On sacrificing the animal and opening the peritoneal cavity an intussusception one and one-half cm. long was disclosed 30 cm. below the pylorus. There was no evidence of a disturbance of blood supply to the intestine.

The pyloric sphincter and antrum were greatly contracted and were very firm on palpation. The fundus and cardiac portions of the stomach were more dilated. When the stomach was opened it was seen to be filled with thick mucoid material which could not be washed off with a stream of water. The crests of the mucosal folds were speckled with punctate hemorrhages. The intestine proximal to the intussusception was filled with the whitish glairy, mucoid secretion from the stomach.

IV DISCUSSION

In the preceding experiments it has been shown that faradic stimulation of the premotor area and certain adjacent parts of the cerebral cortex of monkeys excites the intestines to vigorous motor activity. It seemed difficult, however, to harmonize this fact with the occurrence of intussusceptions following the removal of the premotor and adjoining areas of cortex. A possible solution to the paradox has come from a survey of relevant literature which has indicated that the gut representation in the cortex includes both excitatory and inhibitory units. Cortical ablations appear to cause enhancement of motor activity through the release from the inhibitory components and through a generalized disturbance of the delicate balance normally existing between these mutually antagonistic elements.

1 *Faradic stimulation.* The earliest reference to the effects of cortical stimulation on intestinal motility which could be found was by Bochefontaine⁵ in 1876. He demonstrated that stimulation in the region of the sigmoid gyrus of the dog usually diminished or even completely stopped rhythmic contractions of the stomach. However, the inhibition was often immediately preceded by a strong peristaltic contraction of the entire pyloric region. Movements of the small and large intestines were also found to occur under the influence of cortical stimulation. Peristalsis appeared in different parts of the small intestines in varying intensities, sometimes the duodenum was active, at others, the ileum. Many times peristalsis of the large intestine was so forceful that it carried the fecal contents ahead of it. Exceptionally, cortical stimulation yielded no appreciable results.

Blasko¹⁸ observed that stimulation of the cortex in the region of the cruciate sulcus in the dog caused inhibition of the cardiac sphincter. He obtained contraction of the cardia and the wall of the stomach by stimulating the corpora quadrigemina. Openchowski²¹ localized an area close to the cruciate sulcus from which he elicited opening of the cardia and closing of the

pylorus. Like Blasko, he produced similar changes by stimulating the corpora quadrigemina and also by stimulating the corpus striatum and the lenticular nucleus. Bechterew and Mislawski⁶ by faradic stimulation of the sigmoid gyrus and the area posterior were able to change the condition of the intestinal musculature. Occasionally the occipital region gave similar results but stimulation of other areas was entirely without effect. The usual effects were an alteration in tonus and an increase in peristaltic activity in a few loops of intestine. Stimulation excited contraction and relaxation of the small intestine followed by similar movements in the large intestine.

Osipov²² isolated two points on the sigmoid gyrus anterior to the cruciate sulcus, one at the outer margin of the sulcus and the other close to the inner margin of the hemisphere. From these points he excited contraction of the large intestine. In some animals stimulation was effective at the outer point in other animals at the inner point but not from both and nothing could be obtained from the surrounding cortical tissue. von Pfungen²³ observed an increase in peristalsis on stimulating the sigmoid gyrus and its surroundings. Often however from the same cortical area stimulation inhibited peristaltic movements.

It appears then that stimulation of certain points in and around the sigmoid gyrus results in increased peristalsis, from other points in this region peristalsis is inhibited and stimulation of still other points has no noticeable influence on gastrointestinal motility.

The results of other authors are in complete accordance with our observations. Corneal stimulation in our experience sometimes produced peristalsis in the small intestine and at others ring-like bands of contraction which were not transmitted. In some animals activity could be obtained only in the large intestines. Usually intestinal motility could be influenced from most of the premotor area often from the prefrontal region and occasionally from the postcentral gyrus. Yet not every point within this circumscribed area on stimulation gave increased peristalsis. Inhibition of peristalsis such as was obtained by other experimenters from cortical stimulation was not observed, but this may be due to the fact that there was little peristalsis in the monkey under the conditions of the experiments. In one animal, from which such striking "peristaltic rushes" in the large intestine were initiated, stimulation was effective only from the anterior margin of the superior precentral sulcus.

2 *Ablation and release of junction.* What effects on the gastrointestinal motility have been noted following removal of the influence of the cerebral cortex or certain parts of it?

third appeared to inhibit it, i.e., no effect was noted as long as the electrodes were on the nerve, but motility began as soon as they were removed

Experiment 10 (Intussusception XVII) June 27, 1933 Macaca mulatta Weight 2000 gm After previous extirpation of area 6, faradic stimulation of postcentral gyrus and frontal region excited intestinal activity

Previous operations—January 11, 1933, area 4 was excised from the left hemisphere

February 6, 1933, through a right bone flap area 6 was ablated

Observations upon intestines The right bone flap was reelevated under ether anesthesia and the peritoneal cavity opened. The animal was placed in normal saline at 38° C partly submerging the intestines. The stomach was small. Little material was present in the small intestine and the walls were often in contact with each other. Neither peristalsis nor rings of contraction were observed.

Stimulation of the crater at the site of ablation of the premotor area produced no responses in the extremities or the intestines. However, faradic stimulation with the bipolar electrode of Point 7 (Fig 2) on the postcentral gyrus and Point 8 in the frontal region excited definite responses. Peristalsis involving one or two segments and occasionally a "peristaltic rush" was produced by stimulating these areas. No ring-like bands of contraction were observed.

Stimulation of area 4 caused the usual motor responses in the extremities, but none in the gut.

Several times when the depth of anesthesia became light and ether was administered, the intestine was seen to relax or become atonic. Peristalsis was never excited by the administration of ether, as in some other experiments, but in this one no remarks were made on the presence or absence of an excitement stage.

After the preceding observations had been completed, dial was given intraperitoneally. Two hours later, the small intestine was uniform in calibre, there were no constricting rings. Mild peristalsis was seen in several segments of small intestine for 2 or 3 minutes after the abdomen was reopened. At this time, stimulation of the frontal and postcentral gyri, with the same duration and strength of stimulus, failed to excite any response in the intestines. Stronger stimuli were also ineffective.

In the following experiments area 6 was stimulated two and one-third seconds per minute for two and a half to three hours and movements of the extremities observed. The abdomen was not opened until the stimulation experiment ended. In all three animals the gastrointestinal tract presented signs of excessive

activity and all had intussusceptions of recent occurrence. As far as the gastrointestinal tract is concerned, the conditions were physiological, as the peritoneal cavity was not opened. Another point illustrated is that repeated short faradic stimuli are effective in exciting activity in the intestine.

Experiment 11 (Area 6 III) Macaca mulatta. Weight 1450 gm Repeated brief stimulation of premotor area Autopsy four recent intussusceptions in ileum

Previous experiments—On January 12, 1933, the left motor area had been removed, and on February 23, both cerebral hemispheres were exposed and stimulated faradically. No motor responses could be obtained from the left hemisphere, but the right hemisphere yielded vigorous motor responses which were studied over a period of three hours during which stimuli were applied intermittently to the motor and premotor area.

Autopsy (February 23, 1933) The animal was sacrificed soon after the previous experiment. When the peritoneal cavity was opened, four separate and distinct intussusceptions were disclosed in the lower ileum, the first about 18 inches below the pyloric sphincter, and the fourth, which was an inch in length, was 5 inches from the ileocecal valve. The blood supply to the ileum appeared normal, and all four intussusceptions were clearly recent. The small intestines also showed intermittent rings of spastic contraction similar to those described in the preceding experiments.

Experiment 12 (Intussusception VII Area 6 XVI) March 7, 1933 Immature Macaca mulatta Weight not determined Repeated short stimuli to area 6 with abdomen intact Intussusception at autopsy

Previous experiment—March 7, 1933, under ether anesthesia area 6 was stimulated two and a third seconds per minute for 3 hours by workers who were studying the relation of this area to movements of the extremities.

Autopsy When the animal was sacrificed immediately after the preceding experiment, an intussusception one and one-half cm long was found in the ileum 41 cm below the pylorus. There was no disturbance of blood supply. Eight cm caudally a constricted segment of gut was beginning to enter the relaxed segment in continuity with it, a fold having formed along the periphery opposite the mesentery.

The pyloric region of the stomach was markedly contracted and the body measured only three and one-half cm in diameter. The mucosa was thrown into high folds.

Experiment 13 (Area 6 XV) March 4, 1933 Immature Macaca mulatta Weight not determined Faradic stimulation of area 6 of short duration repeated Intussusception disclosed on opening abdomen

Previous experiment—March 3, 1933 For the purpose of making observations on the extremities, the premotor area was stimulated two and one-third seconds per minute for two and one-

half to three hours. The abdomen was untouched.

Autopsy. On sacrificing the animal and opening the peritoneal cavity an intussusception one and one-half cm long was disclosed 30 cm below the pylorus. There was no evidence of a disturbance of blood supply to the intestine.

The pyloric sphincter and antrum were greatly contracted and were very firm on palpation. The fundus and cardiac portions of the stomach were more dilated. When the stomach was opened it was seen to be filled with thick mucoid material which could not be washed off with a stream of water. The crests of the mucosal folds were speckled with punctate hemorrhages. The intestine proximal to the intussusception was filled with the whitish, glairy, mucoid secretion from the stomach.

IV DISCUSSION

In the preceding experiments it has been shown that faradic stimulation of the premotor area and certain adjacent parts of the cerebral cortex of monkeys excites the intestines to vigorous motor activity. It seemed difficult, however, to harmonize this fact with the occurrence of intussusceptions following the removal of the premotor and adjoining areas of cortex. A possible solution to the paradox has come from a survey of relevant literature which has indicated that the gut representation in the cortex includes both excitatory and inhibitory units. Cortical ablations appear to cause enhancement of motor activity through the release from the inhibitory components and through a generalized disturbance of the delicate balance normally existing between these mutually antagonistic elements.

1 *Faradic stimulation.* The earliest reference to the effects of cortical stimulation on intestinal motility which could be found was by Bochefontaine⁹ in 1876. He demonstrated that stimulation in the region of the sigmoid gyrus of the dog usually diminished or even completely stopped rhythmic contractions of the stomach. However, the inhibition was often immediately preceded by a strong peristaltic contraction of the entire pyloric region. Movements of the small and large intestines were also found to occur under the influence of cortical stimulation. Peristalsis appeared in different parts of the small intestines in varying intensities, sometimes the duodenum was active, at others, the ileum. Many times peristalsis of the large intestine was so forceful that it carried the fecal contents ahead of it. Exceptionally, cortical stimulation yielded no appreciable results.

Hlasko¹⁸ observed that stimulation of the cortex in the region of the cruciate sulcus in the dog caused inhibition of the cardiac sphincter. He obtained contraction of the cardia and the wall of the stomach by stimulating the corpora quadrigemina. Openchowski²¹ localized an area close to the cruciate sulcus from which he elicited opening of the cardia and closing of the

pylorus. Like Hlasko, he produced similar changes by stimulating the corpora quadrigemina, and also by stimulating the corpus striatum and the lenticular nucleus. Bechterew and Mislawski² by faradic stimulation of the sigmoid gyrus and the area posterior, were able to change the condition of the intestinal musculature. Occasionally the occipital region gave similar results, but stimulation of other areas was entirely without effect. The usual effects were an alteration in tonus and an increase in peristaltic activity in a few loops of intestine. Stimulation excited contraction and relaxation of the small intestine followed by similar movements in the large intestine.

Osipov²² isolated two points on the sigmoid gyrus anterior to the cruciate sulcus: one at the outer margin of the sulcus and the other close to the inner margin of the hemisphere. From these points he excited contraction of the large intestine. In some animals stimulation was effective at the outer point, in other animals at the inner point but not from both and nothing could be obtained from the surrounding cortical tissue. von Pfungen³⁰ observed an increase in peristalsis on stimulating the sigmoid gyrus and its surroundings. Often however, from the same cortical area, stimulation inhibited peristaltic movements.

It appears, then, that stimulation of certain points in and around the sigmoid gyrus results in increased peristalsis, from other points in this region peristalsis is inhibited, and stimulation of still other points has no noticeable influence on gastrointestinal motility.

The results of other authors are in complete accordance with our observations. Cortical stimulation in our experience sometimes produced peristalsis in the small intestine and at others ring-like bands of contraction which were not transmitted. In some animals activity could be obtained only in the large intestines. Usually intestinal motility could be influenced from most of the premotor area often from the prefrontal region and occasionally from the postcentral gyrus. Yet not every point within this circumscribed area on stimulation gave increased peristalsis. Inhibition of peristalsis such as was obtained by other experimenters from cortical stimulation was not observed, but this may be due to the fact that there was little peristalsis in the monkey under the conditions of the experiments. In one animal, from which such striking "peristaltic rushes" in the large intestine were initiated, stimulation was effective only from the anterior margin of the superior precentral sulcus.

2 *Ablation and release of function.* What effects on the gastrointestinal motility have been noted following removal of the influence of the cerebral cortex or certain parts of it?

Ott and Field³³ observed that quiet peristalsis in the cat became very active after the brain was sectioned posterior to the thalamus. Similar observations were made by Bechterew⁵. He often noted that defecation occurred soon after the section was made. In decerebrate, vagotomized cats with the intestines floated in normal saline, Lurje²⁶ noted spontaneous contractions of the large intestine over a distance of 5 or 6 cm. The contraction was often of such intensity that the intestine was contracted down like a cord, snow-white due to squeezing out all of the blood. After beginning, the activity often lasted 20 minutes or more. Since the vagus nerve does not innervate the large intestines, certainly not the transverse and descending colons, the results may be considered in the light of the section of the brain.

Pal and Berggrun³⁴ approached the problem in another manner. They stimulated the right vagus nerve 15 seconds and excited contraction of the pyloric region of the stomach, but no movement of the small intestine. Stimulation of the left vagus gave a similar result. Then they made a section through the medulla and stimulated again.

- | | |
|-------|---|
| 11 02 | Complete section of the medulla oblongata |
| 11 10 | Stimulation of R. vagus 10 seconds—with contraction of the stomach there was also a slight contraction of the small intestine |
| 11 12 | Stimulation of L. vagus 10 seconds—definite intestinal peristalsis |
| 11 16 | Stimulation of R. vagus 10 seconds—active intestinal peristalsis |
| 11 35 | Stimulation of L. vagus 10 seconds—vigorous intestinal peristalsis |
| 11 48 | Stimulation of R. vagus 10 seconds—definite intestinal peristalsis |

The table giving the time and result of vagus stimulation makes it evident that the most marked activity appeared 14 and 33 minutes after the operative procedure. This point will be referred to later.

In subsequent experiments Pal and Berggrun³⁴ made more cephalad sections of the brain, stimulating the vagus nerves before and after the section, and observing the effect on intestinal peristalsis. In a series of dogs they made sections of the brain stem in the middle of the thalamus, in another series they made sections anterior to the thalamus immediately behind the head of the caudate nucleus, and finally in one group they extirpated both sigmoid gyri. In every group, vagal stimulation had little effect on intestinal motility before section of the brain, and in every group after section of the brain, vagal stimulation excited lively peristalsis in the small intestine. Often when first observed the intestines were narrow and pale or cyanotic. Following section of the brain the intestines appeared relaxed and redder in color.

One would conclude from the observations of Ott and Field³³, Bechterew⁵, Lurje²⁶, Pal and

Berggrun³⁴ and our own extirpation experiments that certain parts of the cerebral cortex, i.e., sigmoid gyrus and its neighborhood in the dog and cat, and the premotor area and its neighborhood in the monkey, normally exert an inhibitory influence upon intestinal motility. When the influence of the cortex is removed by extirpation, a release of function occurs, allowing excessive and perhaps abnormal intestinal motility.

Release of function raises the question of irritation. The observation of Bechterew⁵ that defecation occurred soon after the brain stem was sectioned behind the thalamus, might be accounted for on the basis of irritation. It is very unlikely, however, that irritation from the section played any part in exciting intestinal peristalsis in the vagus stimulation experiments of Pal and Berggrun. 33 minutes after the operative procedure Sherrington's work on decerebrate rigidity³⁰ and spinal transection indicates, moreover, that irritation from a transection of cord or cerebral substance rarely lasts for more than 10 minutes. Ruch and Watts³⁸, in demonstrating the release of function in the forelimb extensor muscles following postbrachial spinal transection, find that similar signs of irritation disappear within 10 minutes after the lesions were made. Evidences of irritation after injury to peripheral nerves may be somewhat more prolonged, but not longer than an hour⁴.

3 *Intussusception from local stimulation*
Nothnagel²⁸ has shown that by placing a crystal of sodium chloride on the peritoneal surface of the intestine contraction occurs above the point of irritation, whereas complete rest prevails below. Nothnagel²⁹ also demonstrated that it is possible to produce artificial invagination of the bowel in living rabbits by the application of faradic current to the intestinal wall. Cannon¹² states that "the modern conception of intestinal peristalsis was, however, not fully stated until Mall²⁷ pointed out the significance of Nothnagel's observation on intussusception. Nothnagel had reported that the *intussusciptens* portion of the gut, lying below the point of stimulation, folds back, and extends upward over the contracted *intussusceptum* lying above. Thus contraction above and relaxation below seemed so related as to be parts of a single act. And Mall concluded that while a mass in the intestine is causing contraction above, which forces the mass downward and thus stimulates fresh regions above to contract, active dilatation below is at the same time inviting an easy descent. Peristalsis would thus be another example of the mutual adjustment of antagonistic muscles toward efficient action—an example which presents in the neuromusculature of the gut the important principles named by Sherrington—'reciprocal' innervation."

When the premotor area and adjacent parts of the cerebral cortex are stimulated or excited, this local reciprocal innervation appears to be disturbed. In a group of the animals the resulting imbalance was sufficient to excite the production of an intussusception.

4 *Relation of skeletal movement to gut movements* Since the induced activity of the intestines in our experiments was usually associated with slow rhythmic movements of the extremities (from premotor stimulation) the question arises whether the increased intestinal movements have any relation to the movements of the skeletal muscle. It seems improbable that contraction of skeletal muscles could be a primary stimulus since faradization of area 4 caused vigorous movements of the contralateral extremities, but was without effect on the intestines. Also stimulation of the postcentral gyrus and the frontal region anterior to area 4 produced increased motor activity of the intestines but no activity of the extremities.

In several experiments when the depth of anesthesia became light, struggling movements occurred as ether was renewed and this was associated with marked augmentation of intestinal activity similar to that seen in response to stimulation of area 6. As the depth of anesthesia increased, all intestinal movements decreased.

5 *Pathways involved* The pathways by which impulses travel from the cerebral cortex to the intestinal musculature have not been adequately studied. They are clearly extrapyramidal paths because stimulation of area 4 failed to elicit activity in the intestines. Poliak³⁷ has shown that there are tracts from the frontal and precentral cortex to the red nucleus and substantia nigra, possibly there are tracts also to the hypothalamus. In the hands of Beattie² stimulation of the lateral margin of the infundibulum in cats excited marked increased peristalsis and secretion in the stomach provided barbiturates were not used as anesthetics (See also Sheehan and Beattie^{38a}). The usual effects of hypothalamic stimulation similarly could not be elicited in man under avertin anesthesia (Cushing³⁴), and in monkeys under "Dial-Ciba" anesthesia we have been unable to evoke motor responses of the intestine. The failure to obtain responses in animals anesthetized with barbituric acid derivatives is probably attributable to the site of action of the anesthetic, for E and J Keeser²⁰ have shown that the majority of barbituric acid derivatives act primarily upon the hypothalamic and thalamic nuclei.

Although the results in our experiments of cortical stimulation after vagotomy do not admit a definite interpretation it would appear that most excitatory impulses to the small intestine reach it through the vagus, but some also may

reach the small intestine by way of the spinal cord and then by preganglionic fibers of the sympathetic system. Intussusception was never produced in vagotomized animals nor were we able to detect alteration of gastric secretion in such animals.

The clinical implications of these studies, particularly in reference to morbid hunger and the gastrointestinal manifestations of focal and generalized epilepsy will be deferred to a future communication.

SUMMARY

The relation of the cerebral cortex to the motility of the gastrointestinal tract has been studied in a series of monkeys (*Macaca mulatta*) which prior to stimulation of the cortex, had had lesions made in various parts of the cerebral hemispheres. The gastrointestinal tracts of 65 unstimulated or unoperated monkeys were carefully studied as controls. The chief observations and conclusions are as follows:

1 Intussusception with fatal obstruction occurred spontaneously in three healthy monkeys in which the region of the premotor area (area 6) of the cortex had been removed from both hemispheres. Prior to this experience spontaneous intussusception has been encountered only twice in the course of 300 autopsies on monkeys carried out in the laboratory during the past three years, in both instances in acutely ill unoperated monkeys (probably agonal).

2 Carefully controlled faradic stimulation of the monkey's cortex in the premotor region gives rise to active peristaltic movements of the gut, and in 2 experiments with continuous stimulation (1 to 2 minutes) well-marked multiple intussusceptions were produced by this procedure. In three instances stimuli were applied intermittently over a period of several hours (Experiments 11, 12 and 13) and multiple intussusceptions were found on opening the abdomen.

3 Stimulation, brief and prolonged, of the motor area (area 4), which gives rise to vigorous movements of the skeletal musculature, failed to influence the movements of the gut.

4 Stimulation of the premotor area from certain points relaxed the stomach sphincters.

5 Intussusception could never be obtained after the vagi had been sectioned but stimulation of the premotor region in such preparations occasionally caused slight increase in peristaltic movements (the influence of the integrity of the sympathetic pathways was not studied).

6 In some experiments cortical stimulation caused increased secretions of the gastric juice.

7 In one instance (Experiment 10) stimulation of the frontal and postcentral convolution in a monkey from which the premotor area had been removed 5 months before caused increase in peristaltic movements, but not intussusception.

8 It is concluded that the cerebral cortex of monkeys contains autonomic representation for the gastrointestinal tract which is largely restricted anatomically to the premotor area, and that this representation includes both excitatory and inhibitory components

OBSERVATIONS ON THE CHEMICAL AND PHYSICAL RELATION BETWEEN BLOOD SERUM AND BODY FLUIDS*

II The Chemical Relation Between Serum and Edema Fluids As Compared With That Between Serum and Cerebrospinal Fluid

BY D. ROURKE GILLIGAN, M.S., ‡ MARIE C. VOLK, A.B., ‡ AND HERRMAN L. BLUMGART, M.D. ‡

WHETHER cerebrospinal fluid is a dialysate in equilibrium with blood plasma has been

*From the Medical Research Laboratories and the Medical Service of the Beth Israel Hospital and the Department of Medicine Harvard Medical School

This investigation was aided by a grant from the Proctor Fund of Harvard University

†In the literature the term dialysate has been used interchangeably with the term ultrafiltrate in reference to cerebrospinal fluid. The term dialysate has been employed in this communication to comply with the most current usage. This assumption is made that the composition of a plasma ultrafiltrate formed under physiological conditions would be the same or approach closely that of a dialysate at equilibrium (Greenberg D M and Greenberg M. J Biol Chem 94 373 1931)

‡Gilligan D. Rourke—Research Fellow in Medicine Harvard Medical School Volk, Marie C.—Research Assistant Harvard Research Department Beth Israel Hospital Blumgart Herrman L.—Visiting Physician Beth Israel Hospital For records and addresses of authors see "This Week's Issue" page 327

the subject of many investigations since 1912, when Mestrezat¹ first introduced this theory. It is generally held by the proponents of the dialysate theory of cerebrospinal fluid that the chemical composition of such fluid, so far as the major constituents are concerned, is that which would be expected from a simple membrane equilibrium. It seemed that a comparison of the distribution of substances between serum and edema fluids, which we have shown to be simple dialysates in a previous communication², with the reported distribution of substances between serum and cerebrospinal fluid would offer

a basis for testing the validity of the dialysate theory of cerebrospinal fluid

The approximate equality of osmotic pressure as measured by the freezing point of depression of serum and normal cerebrospinal fluid³ is in harmony with the dialysate theory. Since the osmotic pressures of secretions, such as gastric juice⁴ and hepatic bile⁵, are likewise approximately equal to the osmotic pressure of serum the proof of the dialysate nature of cerebrospinal fluid must rest on the conformity of the distribution of the individual substances between serum and cerebrospinal fluid to the distribution demanded by the physicochemical laws of dialysates

The chemical complexity of the serum does not allow an abstract definition of the true chemical state of all of its constituents. Thus, a measure of the total concentration of a given constituent of the plasma may not necessarily represent the amount which will be distributed across a semi-permeable membrane in accordance with the Donnan law of equilibrium. For example, it is well known that the calcium of the plasma consists of both diffusible and non-diffusible forms. The distribution of the total calcium between serum and its dialysates, therefore cannot be interpreted in terms of equilibrium laws alone.

Dialysis experiments between blood plasma and body fluids performed "in vitro" with artificial membranes are open to the criticism that physiological conditions are not reproduced. The proof of the dialysate nature of cerebrospinal fluid must then be based on the conformity of the distribution of substances between serum and cerebrospinal fluid with the distribution of the same substances between serum and other body fluids which can safely be considered dialysates on both a physiological and a physicochemical basis.

The data obtained in this laboratory² and the results of other investigators⁶⁻¹⁰ on the distribution of substances between edema fluids and serum leave no doubt that edema fluids from patients with congestive heart failure, nephritis, carcinomatous obstruction and cirrhosis of the liver are simple dialysates in equilibrium with blood plasma.

It must be considered whether the distribution of substances between serum and edema fluids differs fundamentally from the distribution between serum and normal interstitial fluids. The studies of Heim¹¹ and of Arnold and Mendel¹² on the distribution of certain substances between the serum and lymph of the normal dog indicate that the same laws which characterize the equilibrium between serum and edema fluids also characterize the equilibrium between serum and lymph. When the average values reported by Heim¹¹ are calculated in terms of the water content of the serum and lymph the ratios of the concentrations of chloride, calcium, inorganic phosphate and certain

non-electrolytes in serum and lymph are closely in accord with the ratios of the concentrations of the same substances in serum and edema fluids with similar concentrations of protein². It is clear, therefore, that edema may be considered as primarily a quantitative rather than a qualitative abnormality.

The possibility that one living body membrane may differ in permeability from another living body membrane must also be considered in this analysis. Further, the composition of

†Data for edema fluids taken from paper I of this series (Ref. 2). Values for cerebrospinal fluids calculated from data of the sources indicated in the discussion.

‡Venous blood bicarbonate alone considered in order to compare with venous blood used in studies on cerebrospinal fluid. Mean value for ratio representative of blood midway between arterial and venous is 0.96.

ventricular fluid as well as lumbar fluid must be utilized, since the concentration of some substances in the cerebrospinal fluid varies at different levels¹³. Although the protein concentration of normal cerebrospinal fluid is somewhat less than that of even those edema fluids which contain the smallest amounts of protein, comparison of the chemical composition of edema and cerebrospinal fluid may be made,

since the effect of protein concentration can be estimated from the physicochemical laws of dialysates

The relative distribution of various substances between cerebrospinal fluid and serum and between edema fluids and serum is discussed under separate headings below. This analysis is based on the extensive data which have been reported by other investigators for the distribution of electrolytes and non-electrolytes between serum

FIGURE 1 The relationship between the average differences in the chloride concentrations of certain body fluids and serum (fluid chloride-serum chloride) and the average differences in protein concentration (serum protein fluid protein). The values charted represent the average values in mg. per 100 cc. for the difference in chloride and protein concentration as taken from the literature in the following manner: chest fluid total of twelve observations from our studies³ from data of Loeb⁴ and from Greene⁵; ascitic fluid dogs ten studies by Greene⁶; subcutaneous edema fluid, total of fourteen observations from our studies³; Gollwitzer Meier⁷ and Hastings⁸; cerebrospinal fluid total of 29 observations from Fremont Smith⁹ and Hamilton¹⁰; cerebrospinal fluid with serum proteins averaging 5.5 Gm per 100 cc. six studies from Fremont Smith⁹; lateral ventricle fluids seven studies from Fremont Smith⁹; in vivo dialysates in dogs fifteen studies from Greene¹¹; lymph dogs total of eleven six cervical lymph from Helm¹² and one thoracic duct lymph from Arnold¹³.

and cerebrospinal fluid, on our own data presented previously² and on the data of others for the distribution of substances between serum and edema fluids. Table 1 gives a brief summary of data to be discussed.

CHLORIDE

According to physicochemical laws the concentration of chloride in a dialysate in equilibrium with serum should be greater than the chloride concentration of the serum. It has been established by many investigators that the chloride concentration of cerebrospinal fluid, whether ventricular or lumbar^{13, 14}, is considerably higher than that of the serum of the same patient. The chloride concentrations of various

edema fluids^{2, 6, 7, 8, 9, 10}, of lymph^{11, 12}, of synovial* fluids and of the "in vivo"[†] dialysates of Greene¹⁵ are also higher than those of the sera.

In figure 1 the average excess of chloride in these fluids as compared with the serum (fluid chloride-serum chloride), has been plotted against the average excess of protein in the serum as compared with the fluids (serum protein-fluid protein). It will be noted that the excess of chloride in edema fluids, lymph, synovial fluids, and the "in vivo" dialysate is proportional to the excess of protein in the serum. In contrast, the excess of chloride in cerebrospinal and ventricular fluids is much greater in relation to the serum protein excess than is the case in the simple dialysates. For example, the edema fluid chloride averages approximately 32 mg per 100 cc. higher than the serum chloride, whereas the spinal fluid chloride averages 72 mg higher than the serum chloride when the difference in protein concentrations of the two fluids is 5.4 Gm per 100 cc. (figure 1).

In one instance measurements were made of the chloride concentrations of serum, subcutaneous edema fluid, chest fluid, ascitic fluid and cerebrospinal fluid from a patient with congestive heart failure who had fasted for four teen hours (table 2). The chloride was meas

TABLE 2
RELATIONSHIP BETWEEN CONCENTRATIONS OF CHLORIDE AND PROTEIN IN VARIOUS BODY FLUIDS OF A PATIENT WITH CONGESTIVE FAILURE

	Protein		Excess Chloride	
	Chloride		Protein	
	Gm per 100 cc.	Mgm per 100 cc.	In Serum (Serum Fluid)	In Fluid (Fluid Serum)
Serum	5.1	364

Chest Fluid	0.7	389	4.4	25
Subcutaneous Edema Fluid	0.4	392	4.7	28
Cerebrospinal Fluid	0.02	436	5.1	72

ured by the method of Wilson and Ball¹⁶ and the protein by the method of Dyer¹⁷. The results obtained in this instance are similar to those found by employing average values as in figure 1. The excess of chloride in the cerebrospinal fluid (table 2) is strikingly higher, in respect to the serum chloride, than that found

*Synovial fluid has been included here since data accumulated by Dr. Walter Bauer (personal communication) suggest that this fluid is essentially a dialysate.
†These in vivo dialysates were obtained by Greene and Power¹⁵ through an ingenious method whereby an ultrafiltrate of serum was secured through an artificial membrane interposed in the arterial path of the blood stream of dogs.

in the different edema fluids. Although the cerebrospinal fluid contained only 0.4 Gm. per cent less protein than the subcutaneous edema fluid, it contained 44 mg per cent more chloride (table 2). In contrast, the subcutaneous edema fluid contained only 5 mg per cent more chloride than the ascitic fluid, with a protein concentration 0.5 Gm. lower.

The observed ratio* describing the distribution of chloride between serum and certain body fluids, the excess of protein in the serum, and the distribution ratios calculated according to Van Slyke, Wu and McLean¹³ to conform to the Donnan equilibrium equation are given in table 3. The values for the distribution of chloride between serum and cerebrospinal fluid reported by Muntwyler and his associates¹⁰ and by Fre-

in the case of edema fluids and lymph would make the concentration of chloride in the "free" water of the serum higher than the concentration of chloride in these dialysates, a finding quite contrary to the Gibbs-Donnan law.

It has been noted, by comparison of average values, that the cerebrospinal fluid chloride diminishes as the protein of the serum diminishes^{13, 24}. This relationship is evident in figure 1, where the cerebrospinal fluid chloride excess is less for the series with low serum proteins than for the series with higher serum proteins. A diminishing cerebrospinal fluid chloride excess with a diminishing serum protein excess is in accord with the findings for dialysates. However, the chloride excess in the cerebrospinal fluid from patients with low plasma pro-

TABLE 3

COMPARISON OF THE CHLORIDE DISTRIBUTION RATIOS FOUND WITH THE CALCULATED DONNAN RATIOS FOR VARIOUS BODY FLUIDS

†Value approximated by us from protein difference

discrepancy was obliterated¹⁹. However, this assumption seems invalid, since its introduction by Mont-Smith and Dailey¹² are considerably lower than the theoretical Donnan ratios (table 3). The ratios found by these authors are similar to those reported by others^{20, 21, 22, 23}. The observed chloride distribution ratios obtained for edema fluids (table 2) agree much more closely with the theoretical Donnan ratios, being the same as or slightly higher than the theoretical ratios.

As an explanation for the discrepancy between the observed and the theoretical ratios describing the distribution of chloride between serum and cerebrospinal fluid it has been pointed out¹⁰ that a considerable amount of the plasma water may be bound to the protein or other colloids of the plasma. By assuming a value of 4.3 cc of water per 100 cc of plasma so bound, the

In each instance the ratios express values calculated in relation to the water content of the serum and fluids.

teins is still much too great to comply with the excess of chloride found in edema fluids drawn from patients with low plasma proteins (figure 1). Further, an analysis of data in the literature^{21, 22, 23} on the distribution of chloride and protein between cerebrospinal fluid and serum shows that the variations in individual instances from the average value for the cerebrospinal fluid chloride excess for a given serum protein are very great. It is not uncommon to find differences in the chloride excess of normal cerebrospinal fluids of as much as 20 mg per 100 cc in different patients with the same serum protein concentration, whereas an excess of chloride of this magnitude should on the basis of edema fluid studies, correspond to a serum protein difference of some 4 or 5 Gm per cent.

The cerebrospinal fluid chloride concentration and the serum chloride concentration are reduced in meningitis^{13, 20}. The total osmotic pres-

sue of the serum and cerebrospinal fluid, as measured by the freezing-point depression, are also reduced in meningitis³. The relative reductions of the spinal fluid chloride are at times greater than the reduction of the serum chloride so that the distribution ratio

(Cl) serum

(Cl) spinal fluid

may become more like that found in the case of edema fluids²⁰

Stary, Kial and Winternitz²⁰ and Kral, Stary and Winternitz²¹ found that the chloride concentration of the cerebrospinal fluid diminishes when the serum and cerebrospinal fluid of a patient are dialyzed against one another through a collodion membrane. After dialyzing, the difference between the chloride concentration of the serum and cerebrospinal fluid becomes approximately that found between serum and low protein edema fluids. As early as 1921 Mestiezat²⁰ showed that the chloride concentration of an artificial dialysate is less in respect to the serum chloride than the chloride concentration of cerebrospinal fluid.

Since physiological conditions are not reproducible outside the body, the fact that "in vitro" dialysates of serum from a given patient contain less chloride than the cerebrospinal fluid from the same patient has not, in the past, been considered important evidence against the dialysate nature of cerebrospinal fluid. However, comparative analyses made on the basis of the physiological equilibrium found between serum and edema fluids also lead one to the conclusion that the chloride concentration of cerebrospinal fluid is too high in respect to the serum chloride to accord with the dialysate theory of the nature of cerebrospinal fluid.

BICARBONATE

Hamilton¹ and Muntwyler¹⁰, employing venous sera, and Linder and Carmichael²⁷, employing arterial sera, found that the average bicarbonate concentration of the cerebrospinal fluid is lower than the average bicarbonate concentration of the serum. According to the physicochemical laws of equilibrium, the bicarbonate concentration of a dialysate should be greater than that of the serum representative of equilibrium conditions. Muntwyler¹⁰ found an average ratio

(HCO₃) venous serum

(HCO₃) spinal fluid

of 1.18 as compared with an average ratio

(Cl) venous serum

(Cl) spinal fluid

of 0.86 and a calculated Donnan ratio of 0.94 for the same series

The studies in the foregoing paper² on the distribution of bicarbonate between serum and edema fluids show that the average bicarbonate concentration of edema fluids is greater than that of arterial blood and usually slightly less than that of venous blood. The average ratio

(HCO₃) arterial serum

(HCO₃) edema fluids

was 0.91, the average ratio

(HCO₃) venous serum

(HCO₃) edema fluids

was 1.01, and the ratio of serum of a bicarbonate composition midway between that of arterial and that of venous blood to edema fluids was 0.96 in a series where the average calculated Donnan ratio was 0.955. The value for the average bicarbonate ratio when venous serum was employed agrees with the ratios found by other investigators^{7, 8, 10}. A consideration of the ratios found when both arterial and venous sera were employed indicates that HCO₃ is distributed between serum and edema fluids according to Donnan's law².

Greene and Power¹⁵ obtained an average ratio

(HCO₃) serum

(HCO₃) dialysate

of 0.966 in their "in vivo" dialysate experiments, where the theoretical Donnan ratio was 0.933 and the blood sample representative of equilibrium conditions was known.

Muntwyler¹⁰ suggested that the bicarbonate ratio for spinal fluid might accord more closely with the theoretical Donnan ratio if arterial rather than venous serum were compared with spinal fluid. When the results of Muntwyler¹⁰ are estimated in terms of arterial serum, the bicarbonate concentration of the arterial serum is still considerably higher than the bicarbonate concentration of the cerebrospinal fluid. Further, Linder and Carmichael²⁷ found, on analysis of arterial serum and cerebrospinal fluid in patients with nephritic acidosis, that the bicarbonate concentration of arterial serum is considerably higher than that of spinal fluid.

These studies on the distribution of bicarbonate between serum and cerebrospinal fluid indicate that, unlike edema fluids, the bicarbonate concentration of cerebrospinal fluid is too low to accord with the distribution expected for a dialysate in equilibrium with plasma. The low cerebrospinal fluid bicarbonate concentration cannot be explained by assuming that bicarbonate is bound in the serum, since our data on the distribution of bicarbonate between serum and edema fluids² and the findings of Greene and Power¹⁵ indicate that the bicarbonate of the serum is freely diffusible.

INORGANIC PHOSPHATE

The inorganic phosphate concentration of normal cerebrospinal fluid is approximately 60 per cent less than the inorganic phosphate concentration of the serum^{20, 23, 25}. The cerebrospinal fluid phosphate increases proportionately with the serum phosphate increase in nephritis, so that the ratio of the concentrations remains approximately the same as normally²⁹. On the other hand, the cerebrospinal fluid phosphate is not increased when the serum phosphate is increased in idiopathic hypoparathyroidism³⁰ and is not decreased when the serum phosphate is decreased following the administration of parathyroid extract³¹. In meningitis the cerebrospinal fluid phosphate may increase so that the ratio of cerebrospinal fluid to serum phosphate is increased considerably above the normal value²³.

The phosphate concentration of edema fluids^{2, 31}, and of lymph¹¹ on the other hand is approximately the same as the serum phosphate concentration. In our studies² the average ratio of serum phosphate to edema fluid phosphate, calculated on the basis of water contents of the serum and fluids, was 1.03. In Heim's studies¹² the average ratio of the plasma to lymph phosphate was 0.98.

Walker³², Pincus and his associates³³ and Ellsworth³⁴ employing ultrafiltration through artificial membranes likewise found the phosphate concentration of serum and ultrafiltrate to be practically the same. Strydom and his associates²⁰ observed that when cerebrospinal fluid is dialyzed against serum the cerebrospinal fluid phosphate increases, the concentration in the serum and cerebrospinal fluid being approximately equal at equilibrium.

Walker³² recently observed that the concentration of inorganic phosphate in the cerebrospinal fluid and the aqueous humor of frogs is only 40 per cent of the concentration in the plasma whereas the inorganic phosphate concentration of the frog lymph drawn from peripheral channels is approximately the same as that of the plasma. The inorganic phosphate concentration of glomerular urine is likewise approximately the same as that of plasma³⁵.

The fact that the normal cerebrospinal fluid inorganic phosphate concentration is only 40 per cent of that of the serum, whereas the inorganic phosphate concentrations of "in vitro" and "in vivo" dialysates and ultrafiltrates are approximately equal to that of the serum speaks against the dialysate theory of cerebrospinal fluid.

The discrepancy in the phosphate values which have been found between cerebrospinal fluid and "in vitro" ultrafiltrates has been interpreted by Cantarow²⁹ as due to a distinct difference between the diffusibility of artificial

and of living membranes. This interpretation becomes untenable in the light of the equal distribution of phosphate found between serum and edema fluids lymph and glomerular urine. Further, to ascribe the low phosphate concentration of cerebrospinal fluid to a selective membrane permeability, as differing from the permeability of other living membranes seems untenable, especially in the light of the constancy of the cerebrospinal fluid inorganic phosphate concentration at different levels of the plasma phosphate concentration in hypo- and hyperparathyroidism.

SODIUM

In a large series of carefully controlled studies Fremont-Smith and Dailey¹⁹, and Dailey³⁶ have shown that the concentration of sodium in the water of the cerebrospinal fluid is lower than the concentration of sodium in the water of the serum. Dailey³⁶ found that changes in the serum sodium concentration were reflected by changes in the cerebrospinal sodium concentration, and that the ratio of spinal fluid sodium to serum sodium tended to be constant.

Fremont-Smith and Dailey¹⁹ found an average observed ratio

(Na) spinal fluid

(Na) serum

of 0.96 as against an average calculated ratio of 0.93 in twenty-five cases in which the cerebrospinal fluid was essentially normal in composition. Using the same analytical method as is used by these authors we found the average distribution ratio of sodium between edema fluids and serum to be 0.96² as against a calculated ratio of 0.955. Greene and his associates³ also found an average ratio

(Na) edema fluids

(Na) serum

of 0.96 in a series for which the theoretical ratio was approximately 0.97.

From these data it would appear that the agreement is closer between the observed and calculated sodium ratios for edema fluids than for cerebrospinal fluid. The differences between the observed and calculated ratios for cerebrospinal fluid are not great however. Fremont-Smith and Dailey¹⁹ pointed out that if one assumes that approximately 1 per cent of the plasma water is "bound," this difference for cerebrospinal fluid can be eradicated. For the reasons mentioned previously, this assumption seems invalid.

CALCIUM

The calcium concentrations of normal cerebrospinal fluid and of edema fluid are considerably less than the calcium concentration of serum.

The large excess of serum calcium over edema fluid calcium is ascribed to the affinity of protein for this ion, a calcium-protein combination resulting, which is non-diffusible both through capillary and collodion membranes.

The calcium concentration of normal cerebrospinal fluid averages approximately 50 per cent of the normal serum calcium concentration^{22 25 28 37}. A large number of the reported serum ultrafiltration and dialysis experiments performed "in vitro", and the "in vivo" dialysate studies of Greene¹⁵ give values for the diffusible calcium which are somewhat higher than the cerebrospinal fluid calcium values. Likewise, the calcium concentrations of low protein edema fluids^{2 7 8} indicate that approximately 70 per cent of the serum calcium is diffusible.

In meningitis the cerebrospinal fluid calcium is often increased above the normal²⁸. As was pointed out by Merritt and Bauer²⁸ the increase in the cerebrospinal fluid protein concentration in certain meningitis cases may account satisfactorily for the increase in the cerebrospinal fluid calcium concentration. In other cases the increases are not accounted for in this manner, and would, according to these authors, seem to be a result of the pathological changes in the meninges and choroid plexus.

Kral and his associates²⁵ showed in one experiment in which serum was dialyzed against cerebrospinal fluid that the calcium concentration of the cerebrospinal fluid increased from 48 per cent to 65 per cent of the serum calcium concentration.

It has been shown that the cerebrospinal fluid calcium does not increase appreciably when the serum calcium increases during parathormone administration^{31 38 39}. Further, the cerebrospinal fluid calcium does not decrease appreciably in parathyroid tetany when the serum calcium concentration is strikingly decreased³⁰. Albright and his associates³⁰ have reported studies on a patient with idiopathic hypoparathyroidism in whom the serum and cerebrospinal fluid calcium concentrations were identical, each being 4.5 mg per 100 cc.

In contrast to these findings, the calcium concentrations of edema fluids of low protein concentration³¹ and of lymph¹² show practically the same increase as the calcium concentration of serum during parathormone administration. Arnold and Mendel¹² have further shown that the lymph calcium is decreased as is the serum calcium after parathyroidectomy. These results lead one to conclude that the administration of parathormone causes an increase in the physiologically diffusible calcium fraction of the serum³¹. This conclusion is directly opposite to the conclusion to which one is led if one accepts cerebrospinal fluid as a representative physiological dialysate^{38 39}. Peters⁴⁰ likewise concludes that the logical inference from these

conflicting results^{12 38 39} would be that spinal fluid is not a simple dialysate. He states that if cerebrospinal fluid were to be considered a dialysate the only alternative would be that lymph is not a dialysate, a conclusion against which there is an overwhelming body of evidence.

MAGNESIUM

According to Barrio⁴¹, and to Stary Kral and Winternitz⁴², the magnesium concentration of cerebrospinal fluid averages approximately 40 per cent higher than the magnesium concentration of serum from the same patient. In contrast, Greene and his associate¹⁵ found that the magnesium concentration of the "in vivo" dialysate was lower than that of the serum. Likewise, Greene and his associates⁷ found that the magnesium concentration was lower in transudates than in the corresponding sera. The values for the distribution ratios found by these authors^{15 7} indicate that the serum magnesium concentration is higher than that of the dialysates and transudates partly by virtue of the Donnan laws of distribution and partly because of a bound magnesium compound in the serum, comparable to a bound calcium compound.

Stary, Kral and Winternitz⁴² further found that when cerebrospinal fluid was dialyzed against serum from the same patient, the magnesium concentration of the cerebrospinal fluid became lower than that of the serum. The same analytical method was used for the cerebrospinal fluid before dialyzing and for the dialyzed cerebrospinal fluid.

Whereas according to physicochemical laws and to the values found for edema fluids⁷, the concentration of magnesium should be lower in plasma dialysates than in the plasma, the concentration of magnesium in cerebrospinal fluid is, according to the above-mentioned investigators^{41 42}, higher than the concentration in the plasma.

NON-PROTEIN NITROGEN CONSTITUENTS

The total non-protein nitrogen concentration in cerebrospinal fluid is approximately 60 per cent of the concentration in the serum^{23 43}. In contrast, the total non-protein nitrogen concentrations of edema fluids² and of lymph¹¹ are, when calculated on the basis of water content, approximately equal to the concentrations in the sera. This latter relationship accords with the dialysate nature of edema fluids and lymph, and indicates that the membranes separating these fluids from the plasma are permeable to all of the plasma non-protein nitrogen constituents. Approximately equal creatinine distribution between serum and edema fluids² and approximately equal distribution of urea between serum and lymph¹¹ have been demonstrated.

The low values obtained for the total non-protein nitrogen constituents of spinal fluid are apparently the resultant of the almost complete absence of uric acid^{43 44} and the low values for creatinine^{43 44} and for amino acids⁴⁵. The values reported for the distribution of urea between cerebrospinal fluid and plasma are conflicting^{44 46 47} probably due to the utilization of incorrect analytical methods in certain instances. The results of Galan and Houssay⁴⁷ however, demonstrate practically equal concentrations of urea in blood, spinal fluid, lymph, pancreatic juice and bile in the dog. Cahane and Henrich⁴⁸ have also shown in a recent study of a large series of cases that the cerebrospinal fluid and serum urea concentrations are usually similar.

The above similarities and differences in the distribution of the various non-protein nitrogen constituents of body fluid dialysates (edema fluids and lymph) and serum, and cerebrospinal fluid and serum, do not offer convincing proof either of the dialysate or of the non-dialysate theory of the nature of cerebrospinal fluid. The almost complete absence of uric acid and the low concentrations of creatinine and amino acids might conceivably be attributed to a selective permeability of the membrane separating the cerebrospinal fluid from the plasma. This seems improbable, however, especially in the case of the amino acids. The similarity in the concentration of urea in the cerebrospinal fluid and serum does not necessarily favor the dialysate theory, since urea is likewise distributed practically equally between pancreatic juice and serum, and bile and serum.⁴⁹

SUGAR

Under fasting conditions, cerebrospinal fluid normally contains approximately 60 per cent of the total reducing substances of the serum. Fremont-Smith and his associates²³ found in 22 adult patients that the normal cerebrospinal fluid sugar varied from 49 per cent to 81 per cent of the blood sugar and Stewart¹⁴ found variations from 42 per cent to 82 per cent in thirty normal infants and children. The cerebrospinal fluid sugar is increased when the blood sugar is increased after a meal⁴⁸ and in diabetes⁴⁹, and decreased after insulin.⁵⁰

Ventricular fluid contains, according to Stewart¹⁴, approximately 6 mg more sugar than lumbar fluid, and fluid from the cisterna magna contains on the average 1 mg more sugar than lumbar fluid, indicating that sugar is oxidized in the spinal canal.

By a comparison of data found by Somogyi's sugar method⁵¹ with that found by the Folin-Wu method⁵², Cohn, Levinson and McCarthy⁵³ conclude that the cerebrospinal fluid contains an average of 8 mg per 100 cc of non-glucose reducing substances. Using Somogyi's method Cohn further found that the cerebrospinal fluid

glucose concentration averaged 88 per cent of the whole blood glucose concentration. Transposing Cohn's figures to terms of concentration per unit of water content of cerebrospinal fluid and whole blood, the difference in the glucose concentration of the two fluids becomes much greater.

Equality of glucose concentration in lumbar or ventricular fluid and plasma has not, to our knowledge, been demonstrated.

The concentration of reducing substances in edema fluids, on the other hand, is the same or slightly greater than the concentration in the serum when the values are calculated on the basis of the water content.² Reasons were given in our previous communication for believing that in those cases where the edema fluid sugar was slightly higher than the serum sugar, true equilibrium was not obtained. Power and Greene⁵⁴ likewise found approximately the same concentration of total reducing substances in plasma and in the "in vivo" dialysate and concluded from their results that glucose is diffusible and that there is no evidence of a non-diffusible or colloidal bound form of sugar in the plasma. Equality of glucose concentration in serum and its dialysates must then be expected.

The apparent discrepancy in the distribution of sugar between plasma and cerebrospinal fluid has been explained, as pointed out by Walker³² on two bases: (1) a portion of the plasma sugar is in a form which is not filtrable through the membrane separating spinal fluid from plasma, and (2) a portion of the plasma sugar is utilized by the brain tissue before the fluids to be analyzed are collected.

Walker³² found that the cerebrospinal fluid and aqueous humor of the frog also contained on the average only 60 per cent of the sugar of the plasma, whereas the sugar of the web lymph and the glomerular urine³³ of the frog was approximately equal to that of the plasma. This author points out that since only 5 mg per 100 cc of a total of approximately 40 mg per 100 cc of reducing substances in frog plasma represent non-fermentable sugar, the cerebrospinal fluid of the frog contains considerably less fermentable sugar than the plasma. Walker³² further concludes, "The failure of cerebrospinal fluid sugar to approximate the plasma level after preliminary cisternal drainage (in the frog) argues against the sugar utilization hypothesis which is finally rendered untenable by the demonstration that this deficiency is maintained in depancreatized dogs, whose sugar utilization must be greatly diminished or abolished."

The distribution of sugar between cerebrospinal fluid and serum differs, therefore, from the distribution found between serum and body fluid dialysates or ultrafiltrates, such as edema fluids, lymph and glomerular urine. This apparent non-conformity of the cerebrospinal fluid

sugar distribution with that found for dialysates cannot be entirely explained on the bases of non-diffusibility of the plasma sugar or of modification of the cerebrospinal fluid sugar concentration by tissue oxidation subsequent to dialysis

DISCUSSION

The validity of the dialysate theory of the nature of cerebrospinal fluid has been tested by a comparative analysis of the reported distribution of substances between serum and cerebrospinal fluid and the distribution of the same substances between serum and edema fluids. It has been pointed out in the preceding communication that edema fluid is, beyond reasonable doubt, a simple dialysate in equilibrium with plasma. The comparison between the distribution of substances between serum and cerebrospinal fluid and serum and edema fluids has been amplified by reference to the results reported in the literature for the distribution of substances between serum and lymph and serum and artificial dialysates, as well as by repeated reference to the recognized physicochemical laws for dialysates.

The distribution of chloride, bicarbonate, inorganic phosphate, sodium, calcium, magnesium, non-protein nitrogen constituents and the reducing substances has been discussed. The other constituents of the plasma have not been taken up because there are not sufficient reliable data available on the distribution between serum and the body fluids in question. The results of the many investigators who have measured the relative serum and cerebrospinal fluid concentrations of the substances discussed are essentially in accord with one another.

This study has revealed that the distribution of many substances between serum and cerebrospinal fluid differs markedly from the distribution between serum and edema fluids, lymph and artificial dialysates. The corollary to this is that the distribution of substances between serum and cerebrospinal fluid differs markedly from the distribution demanded by the physicochemical laws of dialysates. It has been pointed out that erroneous conclusions concerning the physiological diffusibility of the constituents of the plasma have been drawn because cerebrospinal fluid has been considered a representative physiological dialysate.

Evidence, on the basis of chemical studies, that cerebrospinal fluid is neither a dialysate nor a simple ultrafiltrate has also been advanced recently by Stary and his associates⁴², by Peters⁴⁰, and by Walker⁴².

SUMMARY

1 The validity of the dialysate theory of the nature of cerebrospinal fluid has been tested by comparing the distribution, as reported in the literature, of substances between cerebro-

spinal fluid and serum with the distribution of the same substances between edema fluids and serum. This comparison has been strengthened by reference to the physicochemical laws of equilibrium and to the reported studies on lymph and artificial dialysates.

2 The distribution of chloride, bicarbonate, inorganic phosphate, calcium, magnesium, non-protein nitrogen constituents, and reducing substances between serum and cerebrospinal fluid differs importantly from the distribution of these same substances between serum and edema fluids. The distribution of sodium differs only slightly.

3 The factors which might explain these discrepancies in favor of the dialysate theory of cerebrospinal fluid have been considered and found inadequate.

4 It must be concluded that cerebrospinal fluid is not a dialysate or a simple ultrafiltrate.

5 The consideration of cerebrospinal fluid as a representative physiological dialysate or ultrafiltrate has led to erroneous conclusions concerning the general physiological diffusibility and chemical state of constituents of the plasma.

FRANCE HONOURS RESEARCH

The President of the French Republic has paid a notable tribute to medical and chemical research by conferring the honour of La Croix de Chevalier de la Légion d'Honneur upon Sir Henry Wellcome LL.D., F.R.S the Founder of the Wellcome Research Institution and its associated research laboratories and museums in which are included The Bureau of Scientific Research Physiological Chemi-

cal and Entomological Research Laboratories and The Museum of Medical Science and The Historical Medical Museum.

Sir Henry Wellcome is a native of Wisconsin and was graduated at the Philadelphia College of Pharmacy. He is President of Burroughs Wellcome & Co (U S A.) Inc New York in whose research and experimental laboratories much original work has been done.

NEW ENGLAND BRANCH, AMERICAN UROLOGICAL ASSOCIATION

SOME DEPARTURES FROM THE BEATEN PATH IN KIDNEY SURGERY*

Experimental Studies

BY NELSE F. OCKERBLAD, M.D.†

AFTER watching the remarkable work of O. J. Dixon^{1, 2} in live muscle transplants in veins and in liver and spleen tissue, I begged his consent to extend this work to the field of kidney surgery and it is with his kind permission that I have been able to pursue these studies and present to you these findings. Not only are these studies and experiments intensely interesting but they are, I believe, capable of a very wide clinical application in human surgery. The use of freshly cut pieces of muscle as a hemostatic is not entirely new. The use of viable muscle grafts and implants is quite new so far as it has been extended to veins and arteries by Dixon and to kidney surgery by me.

Harold Neuhof³ in his monograph in 1923 said, "The free transplantation of striated muscle is not a method of established usefulness in surgery. Except for its hemostatic properties muscle as a transplant has proved of little clinical value. The first work to appear on the subject was a publication by Zielonko in 1874, who transplanted muscle tissue into the lymph sac of a frog and noted the rapid necrosis of the graft without any evidence of regeneration." Neuhof states that experimentally Laeven⁴ was the first to demonstrate that fresh muscle tissue could be successfully used for the control of oozing from parenchymatous organs. Laeven and Jurasz⁵ report two successful cases where wounds of the heart were sealed with a piece of fresh muscle tissue. Earlier than this, however, Harvey Cushing⁶ made use of bits of the temporal muscle freshly cut out and placed upon the oozing points in the exposed brain. He thought that his observation was entirely original but when he found that Sir Victor Horsley⁷, the noted English brain surgeon, had preceded him, he gave him credit in a footnote. Sir Victor had been using it for years but only published a short note upon the subject in 1914. The first and only known man other than Dixon to use viable muscle grafts was Harold Kisch⁸, who used the live muscle graft in a mastoid operation to control the oozing from the bone. Harvey Cushing's⁶ observations were unique and interesting. He found that in brain op-

erations the gauze tips or pledgets of cotton used to sponge adhered to the tissue and when removed the bleeding again started. Casting about for something to leave in the wound he tried cutting pieces of the temporal muscle and found that these would adhere very promptly and check further extravasation better than the gauze or cotton pledgets. He also found that by saving the blood clots that resulted from the hemorrhage after going through the scalp and skull, he could make use of these as a hemostatic. This interesting observation is quoted because of its bearing upon another equally interesting contribution of Eugen Joseph⁹ of Berlin, who published a valuable paper on the subject of muscle implantation in nephrotomy in 1931. Joseph freely states that he got his idea some years before from watching Harvey Cushing using the muscle tissue for hemostasis in brain operations and says that he set his Italian assistant Ciminata¹⁰ to work on the problem as it might relate to the kidney in dogs. Ciminata published his observations in 1924. This was the first work using muscle tissue to control bleeding in kidney operations, but it was all done on non-viable muscle. Ciminata used eighteen dogs in his experiments and in most instances the convex surface of the kidney was resected and in one instance the lower pole was resected. His method was to place the muscle tightly on the bleeding surface and suture it securely in place with fine catgut. About six sutures were taken to fasten the muscle in place. Of the 18 dogs, 13 died, one from peritonitis, three from shock, and nine from suppuration in the region of the kidney. From the five dogs which lived, the following data were compiled. In three days, the muscle tampon had a rough appearance, no bleeding. In six days the muscle tissue could not be seen. The parenchyma wound was covered with a grayish colored slough. In ten days there was a depression of a fibrillar appearing tissue. In 15 days healing was completed, in 20 days, a scarred depression, in 62 days only a superficial scar. The histological findings were interesting and he states that when necrosis of the muscle occurred there was an infiltration of the kidney parenchyma, of the kidney capsule, and of the fat capsule of the kidney. The kidney tissue showed an increase in the intertubular stroma, an enlargement of the uriniferous tubules to-

Read before the New England Branch of the American Urological Association, at Boston, Massachusetts, October 19, 1933.

†Ockerblad, Nelse F.—Professor of Urologic Surgery, University of Kansas School of Medicine. For record and address

gether with hyaline casts, and in a few places anemic necrosis. There was no evidence of regeneration of the muscle fibers. He concluded that if careful asepsis were practiced, it would be possible to secure rapid healing of the kidney after muscle transplant. On the basis of this work of Cimminata, Eugen Joseph⁹ applied

gut sutures. This he says will act as a tampon to prevent bleeding.

In 1917 a very important paper was published from the Laboratory of Surgical Research of the Harvard Medical School by Edward H. Risley¹¹ and although this paper long preceded Eugen Joseph's publication and Cimminata's con-

it to operations upon the kidney in human beings, particularly in cases of nephrotomy for stones in solitary kidneys where there was danger of hemorrhage, and in 1931 reported five cases in which muscle was placed in the nephrotomy wound to control bleeding. He concludes that since nephrotomy has a rather high mortality due to postoperative hemorrhage (8 to 10 per cent in his experience) he proposed to use a piece of the lumbosacral muscle cut the size and shape of the kidney wound and pressed into it and lightly fixed by a few cat-

tribution it was apparently overlooked by both of them as no reference was made to it by either. Risley's work consisted of 12 experiments on dogs, five of which were upon the kidney, three using muscle, one fascia, and one fat. He found that histologically the line of contact of muscle tissue against bleeding surfaces showed an excess of blood platelets and fibrin in considerable degree five to ten minutes after the application and rightly states that its value lies largely in its thrombokinetic content. From his twelve experimental studies he concludes

1 The ideal hemostatic in wounds of parenchymatous origin is interposed muscle tissue taken at the time of operation from the patient's own body

2 Such muscle in order to most effectively stimulate fibrin formation should be jaggedly cut with a knife, not crushed as with scissors, nor should its hemostatic properties be extracted by its contact with salt solution

3 Fascia and fat act to a more limited degree as hemostatics

After seeing the remarkable properties exhibited by the viable muscle grafts, I was very anxious to try some experiments with particular reference to the kidney. The work presented here is only a preliminary report on a problem which we expect to work and report on from time to time through the years without perhaps exhausting all of its possibilities. Possibly you will bear with me while I present to you a rather fragmentary study of a subject that seems to me to be of tremendous importance to us as urologists

EXPERIMENT NO I

The left kidney of a 10 kg dog was exposed and lifted out of the wound. An incision one half the length of the kidney (3 cm) was made 2 cm deep into the kidney in the midline extending well into the parenchyma of the kidney causing profuse hemorrhage. The bleeding was temporarily controlled by finger pressure upon the renal artery. The live muscle graft which had been prepared from the latissimus dorsi muscle $6\frac{1}{2}$ cm long and 2 cm wide was then pressed into the kidney wound and held in place with the fingers for three minutes. The pressure upon the pedicle was released and all bleeding had been stopped by the live muscle graft which had tightly adhered to the wound. No sutures whatever were used to hold the graft in the kidney incision. The kidney was placed gently back in the abdomen and the wound closed in layers. This dog died 20 hours later of the sodium amylal anesthesia. Examination of the operated area revealed no hemorrhage. The muscle graft was densely adherent to the kidney wound, completely obliterating it. The tremendous flow of blood occasioned by so large an incision into the kidney parenchyma and the ease with which the live muscle graft controlled it was a rather dramatic procedure. It was remarkable that the hemorrhage was completely controlled within a space of three minutes and that without the aid of sutures. All other experimenters using nonviable muscle grafts have made use of sutures to hold their tissues in place.

EXPERIMENT NO II

This was quite similar to the first except that the wound in the left kidney was larger and the live muscle graft longer. The kidney pedicle was compressed with the fingers and the viable

muscle graft was pressed into the wound in the kidney. In this case the kidney incision was so large that the prepared muscle graft did not quite cover the edges of the wound so that pressure had to be maintained for eight minutes before the pedicle could be released and we were sure of complete hemorrhage control. The kidney was gently replaced in the abdomen and the wound closed in layers leaving the muscle graft passing through the abdominal wall and into the peritoneum. This dog was not sacrificed until 60 days later when it was found that there had been neither infection nor hemorrhage and the muscle graft had not degenerated in any way and it still adhered to the kidney.

EXPERIMENT NO III

The left kidney of a 17.5 kg dog was exposed by a loin incision. A piece of live muscle was prepared 7 cm in length and made ready for use. The kidney was delivered and an incision 2 cm long was made, cutting out a wedge shaped piece out of the lower pole of the kidney. The muscle graft was spread out flat over this wound and pressed down into it. After five minutes the graft adhered and the hemorrhage ceased. Due to the position of the graft in relation to the kidney wound it was feared that the graft might be peeled out of the wound when the kidney was replaced, so a single mattress suture was placed to prevent this from happening. The dog completely recovered from the operation.

EXPERIMENT NO IV

In a 10 kg dog, the right kidney was exposed. A viable muscle graft 8 cm long was prepared from the external oblique. The kidney was split from pole to pole down to the kidney pelvis. The muscle graft was pressed down into the wound while holding the pedicle compressing it with the fingers. After two minutes the pedicle was released and the blood welled up from the wound. Pressure was maintained for another four minutes when it was again released. This time the bleeding was controlled. No sutures were used. The dog was sacrificed 60 days later because of distemper. The muscle graft was still good and showed no signs of degeneration.

EXPERIMENT NO V

Dog No 43. A left rectus incision was made 12 cm in length. A piece of the left rectus muscle was prepared as a viable muscle graft. The left kidney was then delivered out of the wound and an incision made cutting off the lower third of the kidney. The pedicle was compressed with the fingers and the viable muscle graft applied. The graft adhered promptly to the cut surface but was not quite large enough so that a supplementary smaller graft had to be added. This was not a viable graft. It adhered to the cut surface and in five minutes all bleeding had

ceased. The dog died 31 days later and the examination showed no apparent cause of death. The viable muscle graft was still in place and the muscle showed no degeneration. The non-viable piece had sloughed off and completely disappeared. There had been no hemorrhage and no infection.

EXPERIMENT NO VI

Dog No 39. The right kidney of a 16.3 kg dog was exposed by a lumbar incision and delivered out of the wound. The pedicle was stripped of its fat and coverings so that the renal vein was exposed. A viable muscle graft was prepared from the external oblique. An incision was made into the renal vein with the point of a sharp knife 3 mm in length. Blood poured out in a steady stream. The muscle graft was pressed down over the wound in the vein and it immediately adhered and the bleeding ceased within three minutes' time. Because of the fact that there seemed to be some tension on the viable muscle graft where the kidney was replaced, it was cut off from its attachment and placed back with the kidney. The dog recovered. No hemorrhage, no infection. The dog was killed because of a distemper epidemic among our animals 41 days later. The muscle had degenerated but was still adherent to the renal vein. This remarkable experiment had a practical application a short time later when, in the course of a rather complicated pyelotomy for a large stone in a human being, I accidentally injured the renal vein so that it was badly torn. I immediately made pressure on the vein while a muscle graft was prepared and applied the muscle to the wounded vein and made steady pressure for three minutes. The graft adhered and the bleeding ceased. The kidney was replaced and the patient recovered. I believe that, in injuries to the renal vein in the course of operative procedures, the application of live muscle to the wounded vein is a much simpler and very much safer procedure than an attempt to suture the vein. The second human case is one in which I did a nephrotomy for stone, having incised the lower pole of the kidney. A live muscle graft derived from the quadratus lumborum was prepared and placed in the wound and the wound closed over it by the usual means of chromic mattress sutures with pieces of fat in the loops to prevent cutting. I did not have quite the requisite courage to place the graft without sutures although I feel perfectly certain that it would have adhered as firmly as it did in the experimental animals. Eugen Joseph did not trust any of his nephrotomies without sutures. How far one may go in this direction, I hesitate to say without further experimental work. I am not yet advocating the interposition of muscle grafts, viable or non-viable, in human surgery even though in these two cases cited it seemed to be a safe procedure.

EXPERIMENT NO VII

The next experiment was on a dog in which I had previously operated the left kidney. The right kidney was exposed by a lumbar incision and the kidney delivered. A live muscle graft 7 cm in length was prepared from the external oblique muscle. The kidney was split down to the pedicle from pole to pole. The pedicle was compressed with the fingers and the thick muscle graft laid in the wound. The kidney was then bound together with Lowsley's ribbon catgut 5/8" wide, one on either side of the hilus and these tied rather securely. The muscle graft contracted somewhat so that it seemed necessary to place one mattress suture near the end of the graft, spoiling what would otherwise have been a perfect demonstration of the usefulness of this unique closure method of Lowsley.¹² I was rather fearful that, in so complete a division of the kidney, nothing would prevent fatal hemorrhage, but the combination of the live muscle graft and Lowsley's bands prevented hemorrhage. This dog weakened and was ill so that 27 days later we sacrificed the animal and found that there were many adhesions to the surrounding organs. There had been no hemorrhage or infection. One of Lowsley's bands had completely disappeared. Parts of the second one could be seen not quite completely absorbed.

I feel certain that Lowsley has hit upon an idea that will prove of great value in kidney surgery and I intend to pursue the experimental work farther in this direction until I have some more definite data to present. So far this seems to promise much in the way of improved technique in nephrotomy. Much more remains to be done in this interesting and fertile field.

The applications that I see so far as they relate to the field of urology are many. In kidney surgery, I believe this method of live muscle grafts may have considerable application particularly in nephrotomy. In blood vessel surgery, especially injuries to the renal vein or to the aorta, it will replace attempts at suturing these fragile vessels in such difficult situations. In hemorrhage from the urethral bulb or even the prostatic bed, live muscle grafts can be freely used. In wounds of the corpora cavernosa or even the use of live muscle grafts in fibrosis of the corpora cavernosa to act as a framework upon which a new endothelial structure can be formed is not entirely visionary.

I have not touched upon the physiology of the remarkable hemostatic properties of live muscle tissue because that is pretty well known and much work has been done to attempt to explain all the processes, though our knowledge of these processes is not as yet complete. The pathology which the live muscle graft induces in the kidney wounds and the microscopic pictures are not yet complete but are being studied and will be presented at a later date.

DISCUSSION

DR. WILLIAM C QUINBY I have been most interested in the presentation which Dr Ockerblad has been kind enough to make to us, for it brings up for discussion many different phases of both physiology and surgery

In the first place we have to deal with the question of the physiology of the coagulation of the blood which is still a rather abstruse matter It is known that muscle tissue, when cut away from its support, is quick to produce coagulating substances It is this which one takes advantage of in using muscle tissue for hemostasis

Dr Harvey Cushing, now Professor of Surgery at New Haven, once studied this question in detail Inasmuch as fibrin is an element in the coagulation of blood he tried to devise various methods of applying fibrin, taking blood collected sterily and whipping it into sheets of fibrin We used these for a while in the laboratory at the Harvard Medical School and once or twice I used it clinically as a method of applying a quick styptic to parenchymatous bleeding Unfortunately it was not successful The fibrin acted as a foreign body so that the wounds did not heal by first intention though hemostasis was satisfactory Muscle itself, however does do exactly what Dr Ockerblad has said It promotes coagulation of blood The factors which surround its successful use are several, however

In the first place the bleeding must not be too profuse As Dr Ockerblad has stated, bleeding must be controlled in the beginning by pressure on the renal pedicle In other words, it is not possible to make an incision into the kidney and remove whatever is necessary or make for instance a heminephrectomy without having previously prepared that kidney to such an extent that one has control over the vascular pedicle, because the mere force of the arterial bleeding will wash the muscle graft away so that it has no chance to act Pressure, therefore, is a factor in controlling hemorrhage from such parenchymatous organs as the kidney the liver and possibly the spleen even more important than Dr Ockerblad has suggested

There are various other methods of controlling hemorrhage from the kidney of which one is the use of the high frequency electric current. For instance, having made the kidney sufficiently mobile to control the vascular pedicle if one then opens the whole kidney by a complete or partial nephrotomy controlling the vascular pedicle actually picks up the important bleeders on very fine hemo-

stats and then applies the high frequency electric current to the handle of the hemostat a sufficient control of the immediate hemorrhage will frequently be secured

In closing I wish to congratulate Dr Ockerblad on his splendid work.

DR. RICHARD CHUTE May I ask Dr Ockerblad when he discusses his paper if he will comment on whether there is any value whatsoever in non viable tissue I take it he means viable as attached at one end and I wonder if non viable tissue has any value

DR. J H CUNNINGHAM What I have heard this evening impressed me particularly because it is a general principle rather than a procedure that is devoted entirely to our specialty Any general principle, I think, that may be applied to our specialty is far more important

Being conversant with the literature that Dr Ockerblad has presented from time to time, I have always been impressed with one fact—he always seems to hit the nail on the head I think his kidney clamp is a good example Now when he comes with a general principle applied to something that we are all confronted with, although we have overcome our difficulties by methods already in use, this new principle of controlling kidney hemorrhage is certainly something that is a great addition to what we already know

The conservation of kidney tissue has always been to my mind a very important thing, and the employment of mattress sutures to close kidney wounds has always been in my opinion a procedure which probably destroys considerable kidney tissue We have been trying to get away from this by various improvements in technical procedures The idea of implantation of fat with less suture in the kidney would, I think, have been helpful Probably all here have had instances where the patient's general condition was such that we have tamponed the kidney incision without any suture, but with control of bleeding I recall several instances where I have used the kidney elevating clamp, I believe it is called, to compress the kidney and stop hemorrhage This clamp left for 24 hours obviates any suture However, to have a general procedure such as we have heard of tonight for our use advocated by somebody who has not too much theory, but a very definite viewpoint of practical application is I think, of extreme importance I am delighted to have had this new method of controlling kidney incision hemorrhage added to the various methods that I already employ

DR. AUGUSTUS RILEY I believe the speaker's ideas of hemorrhage control express great thought. In the past few years I have done partial nephrectomy in a few selected cases, and was able to control the hemorrhage without much, if any, difficulty with properly placed sutures One case especially I recall at the present time A heminephrectomy was done and the hemorrhage was controlled very easily with deeply placed sutures Apparently the half of the kidney left was not damaged to a great extent, because a split function done some time after the operation, was good and compared well with the non-operated kidney in proportion to the amount of kidney tissue left at the time the heminephrectomy was done

I agree with Dr Cunningham, our method of hemorrhage control in kidney surgery may be rather crude in appearance, but it does the work.

I am glad to have heard the speaker's paper, am glad to know his method of controlling hemorrhage and will certainly try it when the opportunity presents itself.

DR. GEORGE G. SMITH I do not know of any paper which has been presented here that I can remember which has in it so much that may prove of value to men who are doing operative work on the kidney and doing general operative surgery. It seems to me that Dr. Ockerblad has brought forward here a new principle which will be more than helpful.

I would like to ask Dr. Ockerblad if he has any idea as to whether, in using this in a kidney in which there is sepsis, say after removal of a stone from a fairly septic kidney, the muscle graft would hold in the same way or whether the sepsis would be a factor operating against it.

DR. OCKERBLAD (In closing) Dr. Smith has raised the question of sepsis in connection with muscle implants and that is right in line with the query about live muscle grafts. One of the main points about live muscle grafts is that they apparently are not so subject to infection as the detached pieces of muscle. The detached muscle grafts are frequently the subject of infection. One of our workers did nephrotomies on six dogs and used detached muscle as implants in these nephrotomy wounds and three of the dogs developed infection. In over thirty other dogs we have had only one infection with live muscle grafts. Apparently the live muscle grafts have considerably greater resistance to infection.

In answer to the question which Dr. Smith has brought up as to whether we have tried them in infected wounds, I can only say that we have not done so as yet. We will have to deliberately make these infections in dogs and then implant muscle tissue to see what happens but I fear that muscle tissue cut off this way from its blood supply will act as a culture media and will not aid in hemosta-

sis so well as it would when still attached to its blood supply.

Dr. Quinby has been very complete in his discussion. His statement that fibrin had been a failure as a preparation in advance is perfectly true and I carefully avoided this whole subject inasmuch as there have been volumes written on it. There seems to be no end to it if one starts a discussion of the various theories of the formation of blood clot. However, these essential hemostatic agents cannot be prepared and stored up in advance. There must be something in the piece of live muscle or those freshly detached which those prepared juices do not have.

Pressure certainly has a marked effect in controlling hemorrhage in parenchymal tissue like the spleen, liver and kidney although I think the kidney tissue is quite different from either spleen or liver and perhaps the bleeding in kidney tissue is a little more easily controlled than that in spleen tissue, but pressure was not a factor in the veins which Dixon opened and pulled the muscle strips through. The long live muscle grafts stopped the hemorrhage in that situation just as readily as they did in the kidney structure. Take the adherence of these muscle flaps to the vein and to the cava. In these places we used just enough pressure to make them stick fast and the graft adhered permanently in a very short time.

Dr. Chutes question about non viable muscle tissue, I have perhaps covered.

There is much more work to be done on this very important subject and this presentation is merely a summary of the work we did last summer.

I want to thank you for your kind attention and your generous participation in the discussion.

WHERE THE DEATHRATE HAS INCREASED

On the basis of their crude deathrates, three diseases—cancer, diabetes and heart disease—recorded higher mortalities in 1933 than ever before. The great bulk of the deaths from these diseases occurs among persons in the higher age ranges—specifically from age 55 on. Accordingly it is necessary in considering the course of the deathrate from these conditions (especially with respect to what has transpired during recent years) to take into account a change that has occurred in the age distribution of Metropolitan Industrial policyholders as in the general population. There has been a shift whereby a larger proportion of the insured is finding itself in the higher age groups. This increase in the average age of this group in itself tends to raise the crude deathrate of these three diseases. Its effect, in fact, has been so marked that it is necessary to use standardized deathrates which make allowance for changes in age distribution in order to make valid comparisons of the 1933 deathrates with those of previous years. When standardized rates are prepared we find that the 1933 cancer and diabetes deathrates are higher than ever previously recorded although the rise is shown to have been by no means so sharp as the crude figures would indicate. The heart disease deathrate on the other hand is actually lower than for both 1930 and for

1911, the year in which the Metropolitan began to compute mortality rates for individual causes of death and shows only a slight rise as compared with that for 1932.

When analysis of what has happened in recent years is extended to the several types of cardiac impairments, we find much that is encouraging in the trend of the heart disease deathrate. First, only in the higher age groups is the mortality increasing and the heart disease prevailing in this period of life is very largely of the arteriosclerotic or senescent type. Accordingly the increased number of deaths is due in great measure to the aging of the population whereby more and more persons attain those higher ages where senile degeneration of the heart is the most common cause of death. This may be a by-product of the increase of the average duration of human life. The encouraging side of the picture is a marked declining tendency in the death rate from the endocardial and valvular affections in early adult and middle life. These types of cardiac disease have their origin largely in acute rheumatism, syphilis, certain communicable diseases of childhood and focal infections. We may look forward to continued improvement as the result of the decline which is going on in the incidence of these controllable diseases.—*Bulletin Metropolitan Life Insurance Company*

END-RESULTS IN EXOPHTHALMIC GOITER*

Patients Treated in Pre-Iodine Days

BY HELEN SINCLAIR PITTMAN, M D †

THE introduction of the therapeutic use of iodine has revolutionized the treatment of exophthalmic goiter. It has seemed worth while, therefore, to investigate the present condition of several patients who were treated for that disease before iodine was introduced. For the purpose of this study an attempt has been made to follow the records of 168 patients treated at the Massachusetts General Hospital prior to 1923, the year in which Plummer's¹ first article on the use of iodine in toxic goiter appeared. The patients comprising this group were unselected. They received their treatment between 1913 and 1923. The minimum follow-up period is, therefore, nine years. An effort has been made to trace all individuals treated during those years. All the 168 patients in this series were followed for a period of not less than six months after leaving the hospital, and most of them for at least two years. Hospital patients, however, in a city are usually those of a floating population and it is impossible at the present time to locate about half of them. Of the 168 patients treated in the years mentioned, 94 have been located. Of these, 20 have been unable to return to the hospital but have written of their condition, two have been reported from outside sources, 8 are dead and 64 returned. Each individual who returned had basal metabolic rate determinations and any special examinations (electrocardiogram, blood, urine and so forth) indicated.

There is thus information concerning 94 individuals, or 55 per cent of those treated.

Before the introduction of iodine thyroid surgery in Graves' disease was not the simple matter which it is to-day. The operative mortality rate in Graves' disease at the Massachusetts General Hospital in the years 1909-1914² was 15 per cent. From 1920-1921 this had been brought down to three per cent.

There were three accepted modes of treatment:

- 1 X-ray alone. This was given to 61 patients, on 38 of whom there are recent data.
- 2 X-ray combined with surgery. This was employed in 35 patients, on 26 of whom there are recent data.
- 3 Surgery alone. This was practiced on 67 patients, on 30 of whom there are recent data.

*From the Thyroid Clinic of the Massachusetts General Hospital.
This study was made possible by a grant from the Proctor Fund for the Study of Chronic Disease of the Harvard Medical School.

†Pittman Helen Sinclair—Assistant in Medicine Massachusetts General Hospital. For record and address of author see "This Week's Issue" page 927.

In evaluating the status of the patients this year, I have grouped them according to the treatment which they received. Of the original series of 168 patients, five records have been destroyed, making the classification of treatment based on a series of 163 instances.

Group I, comprising 38 individuals, were treated by x-ray alone. Holmes³ wrote in 1919 that it is possible to decrease the activity of the thyroid gland and probably to destroy its glandular structure by exposure to the Roentgen ray. Such treatment applied in cases of thyrotoxicosis produces relief of symptoms and shortens the course of the disease. He felt at that time that the Roentgen ray accompanied by rest should be tried in all cases of thyrotoxicosis and should be continued for a sufficient time to at least cause involution of the thymus, before resorting to surgery. The dangers of x-ray are less than those of surgery and in the milder cases it obviates the necessity of interfering with the daily life of the patient. If relief was not obtained after nine treatments, or if for any reason it was desirable to hasten the process, surgery might be recommended. The previous treatment by Roentgen rays will have been of benefit in reducing the operative risk by destroying the thymus gland. In a later article Holmes⁴ gave as indications for operation, the failure to respond as indicated by a lowering of basal metabolic and pulse rates with corresponding gain in weight after six months of treatment. Means and Holmes⁵ reported that about two thirds of their cases treated by this method showed recovery or improvement. Read⁶ has recently reported the present status of eight patients of a series of 36 treated prior to 1924, all of whom are now well. Hayes⁷ found that of 100 consecutive, unselected, private patients treated by x-rays in the years 1911-1926, 62 per cent were cured in 1927. No individual in his series developed myxedema.

1 In the present series there are 38 instances of treatment by x-ray alone. Of these 26 are cured of their thyroid disease, four are dead, three have chronic mild hyperthyroidism, four are myxedematous but controlled, and one has a severe complication.

The last patient mentioned presents one of the most serious complications of hyperthyroidism. After eight treatments she was completely relieved of her thyrotoxicosis but had a severe residual exophthalmos which, because of corneal ulceration, ultimately required bilateral enucleation. This case was reported by Lahey⁸.

2 Twenty six individuals in the present series were treated by x-ray in conjunction with

surgery, one is dead, 22 are well, and three have chronic mild hyperthyroidism

Group III is made up of 30 individuals who were treated by surgery alone. This was, in those individuals who were toxic, a series of graded operations: ligation of one or both superior thyroid arteries, hemithyroidectomy or subtotal thyroidectomy. With patients prepared for operation by bedrest alone or combined with the administration of quinine hydrobromide, the operative risk was too great, in most instances, to allow of the single operation of sub-total thyroidectomy commonly employed at the present time. The single operation of choice was hemithyroidectomy. In 1920, Judd⁹ obtained information from 88 individuals out of a series of 100 consecutive exophthalmic goiter patients on whom he had operated in 1914 (64 primary or secondary ligation, 36 primary thyroidectomy). Sixty-five and eight-tenths per cent were cured and 15 per cent had died from all causes during the six years. Hueck¹⁰ was able to follow 54 patients of a series of 79 treated between 1912-1925 by surgery alone or by x-ray in addition to surgery and found that 78 per cent were able to do full work.

In our series, 30 individuals were treated by surgery alone. Of these, three are dead, 21 are well, two have chronic mild hyperthyroidism, three have myxedema, and one is in a state mental hospital with a major psychosis.

The results obtained in the three groups are compared in table I.

now, 15 years after her last radiation presents the picture of chronic mild hyperthyroidism with a +20 per cent rate. Two other individuals (E N No 48 and E D No 316) were treated over a period of four years and are now well.

Of those treated by x-ray combined with surgery, 15 were given radiation before operation, five after, three both before and after, and in two individuals radiation was done following ligation of the thyroid arteries and before hemithyroidectomy. In this group the larger number (14) required from six months to a year for treatment, four completed their treatment in less than six months and one (M G No 1382) was treated over a period of three years. In 1922 she had an initial rate of +40 per cent, a right lobectomy with removal of the isthmus was done in April of that year without affording her permanent relief. Four Roentgen ray treatments were given in 1924 but it was not until February, 1927 that her rate dropped to a normal level (-3 per cent). At the present time she is cured of her thyroid disease but at the age of 66 years she has arteriosclerotic heart disease with a blood pressure of 160/90.

Of the individuals treated by surgery alone, 19 had one operation (four subtotal and 15 hemithyroidectomies), five had two operations, five were operated upon three times and one (M L No 326717) had five operations, the first in 1906, the last in 1913. At the present time she has a basal metabolic rate of +5 per cent with a pulse of 69. She gives evidence, how-

TABLE I

Treatment	Original Series	Recent Reports	Well	Chronic Hyperthyroidism	Myxedema	Dead	Special
X-ray alone	61	38	26 (68%)	3	4	4	1
X-ray combined with surgery	35	26	22 (86%)	3	—	1	—
Surgery alone	67	30	21 (72%)	2	3	3	1
Records destroyed	5	—	—	—	—	—	—
Totals	168	94	69 (73%)	8	7	8	2

THE RECORDS OF 168 CASES

Discussion. In the x-ray group 18 individuals received treatment for a period of between six months and one year. Two individuals received each one treatment only (I C No 1649 and A M No 1170), both are now well. One of the most striking points in the records of this series of individuals is the length of time required for some of them to attain a normal metabolic level after the beginning of treatment. A L No 25 had an initial rate of +83 per cent in 1915 during which year she had seven x-ray treatments and never became normal until 1922 when she had a rate of +4 per cent. At present she presents a cure with a rate of -4 per cent and at the age of 50 years has no evidence of cardiovascular disease. J B No 68 received 29 treatments over a period of four years and

ever of hypertensive heart disease with a blood pressure of 238/130.

Summary and Conclusions. Recent data (64 examinations, 30 letters) are presented on 94 individuals out of a series of 168 patients treated for exophthalmic goiter between 1913 and 1923. These individuals were treated by one of three methods: x-ray, x-ray combined with surgery, or surgery alone. Sixty-nine (73 per cent) are well, eight have chronic mild hyperthyroidism, seven are myxedematous, one individual has had a bilateral enucleation for corneal ulceration secondary to a persistent severe exophthalmos, one is in a state mental hospital. The most satisfactory results have been obtained in the group treated by x-ray combined with surgery (86 per cent cures). In the groups treated by x-ray alone or surgery alone, there was very little dif-

ference, 68 per cent cures in the former and 72 per cent in the latter. The period required for relief of symptoms varied from a few weeks in two instances to a maximum period of seven years, with no consistent difference in the three groups in time required from beginning of treatment to cure. In the majority of individuals relief from symptoms was obtained in from six months to one year, a far longer time than is now usually required for cure by subtotal thyroidectomy in the iodized patient. The methods employed in the years studied are shown to have given good results after a period of not less than nine years, but each method entailed a longer period of treatment than do present methods.

FLAT FOOT

An Anatomical Reconstruction

BY FREDERIC JAY COTTON, M.D.,* AND GORDON MACKEY MORRISON, M.D.*

The vast majority of flat feet call for no operation.

Many flat feet involve bony change, these cannot be "reconstructed" in any literal sense, must be operated on if need be by wedge operations, etc. But in others in which in Brack-

OPERATION FOR FLAT FOOT

Upper figure Shows the open astragalo scaphoid joint—the cut (a) above the supporting ligament carried forward across bones and articulations.

Lower figure The foot corrected, the bone-ligament flap carried forward. The rear end of the scaphoid in the graft (b), the scaphoform articulation (c), the cuneiform metatarsal (d) are all carried forward one-half inch—and the whole strip pegged in place.

ett's phrase "the bony architecture is unchanged" one can reconstruct. Among these is a type often seen in young men in which a long lax foot, pronated flat, shows perfectly evident relaxation of ligaments not presaging much chance of correction by exercise. Only in such cases is this operation to be considered. It rests on the fact that the weight is transmitted from the top of the astragalus through its downward rotated head to the supporting calcaneo-scaphoid ligament, a very definite and very strong structure even when relaxed. The operation consists in transferring the scaphoid at-

tachment of the ligament farther forward so as to tighten up the ligamentous support. The technique is shown in the accompanying cut.

The astragalo scaphoid joint is opened and a rather broad, thin osteotome, pointing outward and about 35 degrees downward, is driven through to the plantar surface of the bone, separating (roughly) one quarter of the scaphoid.

The line of the cut is continued forward, disregarding joint intervals, to $\frac{3}{4}$ inch in front of the base of the first metatarsal.

If then the foot is corrected into proper position in the direction of cavo-varus, then the bony flap, containing parts of scaphoid, of internal cuneiform and of metatarsal base, is easily slid forward to a new hold. The bony flap is loosened, never dug out of its bed on the under side.

The front end, the metatarsal piece, may be trimmed off as superfluous, and the main flap is to be pinned in its new place with small ivory or bone pegs.

CASE

J. D. (man now 27 years old), operated on at the Boston City Hospital in 1920, was examined in July, 1933. One foot only had been operated on (with expectation of doing the other after an interval). Thirteen years after it showed a foot perfectly normal in stance and mobility. The left foot still showed a lax flat foot of extreme type with troublesome weakness.

In a very few other cases treated the result was good, but none other followed up for a long time.

The operation in no way interferes with lateral rotary motion in the subastragaloid joint. The only drawback is the need of waiting for solid bony union before unrestricted unsupported weight bearing is resumed.

This operation is applicable to only a small selected group of cases, it is only one of many corrective measures for the relief of flat foot.

INTERN TRAINING IN MASSACHUSETTS*

By the Committee on Medical Education and Medical Diplomas
of the Massachusetts Medical Society†

IN this country it is generally agreed that one of the most significant phases of medical education is that which has to do with the training of hospital interns and that the future progress of medicine depends in no small degree upon the way in which these interns are trained. During 1933, more than 5000 medical school pupils received postgraduate education as interns in our various hospitals in New England alone, 510 interns were at work in the fifty-nine hospitals approved by the American Medical Association to offer such training.

The Committee on Medical Education and Medical Diplomas of the Massachusetts Medical Society, recognizing the importance of internships to medical progress, has considered it desirable to make a preliminary survey of the internships available in this state in order to ascertain if possible, how our internships are filled, whether they are good, bad, or indifferent and whether any suggestions can be offered to make them more valuable. The results of this survey are reported here.

MASSACHUSETTS INTERNS

Thirty-one Massachusetts hospitals are approved by the American Medical Association for intern training and help to educate each year a group of 312 doctors. During 1933, these doctors assembled from far and wide, but were mostly graduates as might be expected, of Tufts, Harvard and Boston University. In addition, thirty-six other American Medical Colleges, two Canadian and three foreign schools, sent pupils to be trained here. Two hospitals have attempted an experiment of very questionable usefulness by receiving as interns doctors from unrecognized medical schools.

The interns of 1933, presumably, were a typical group. On the whole, they were recent graduates, migrating as quickly as possible from the shelter of their various schools, to the broader experience of hospital life. One man who graduated in 1925, received an appointment. He was by far the oldest man on the list, he had come to us from the West and was taking this means to obtain in Boston the postgraduate training in surgery that he felt he needed.

Five of our hospitals claim not to discourage the appointment of women interns. In spite of this, but ten women interns were enrolled. This fact perhaps deserves comment since now-

adays nearly five per cent of all medical students graduating each year are women. A fair annual quota of women for Massachusetts to enroll as interns would be nearer fifteen than ten. Good women students can be used very advantageously and should be given better opportunity.

If the 312 Massachusetts interns are regarded as a class, it is interesting to note how this class is made up scholastically. Half of these students graduated in the upper third of the medical schools whence they came, and only a fifth in the lower third. Thus Massachusetts cannot complain of the intellectual abilities of her interns.

MASSACHUSETTS INTERNSHIPS

The quality of the Massachusetts internships which are available is a more difficult matter to analyze. In general, internships are of three types. The straight "medical" or "surgical," the "rotating" and the "special service" internship. They vary in length from one to two or more years' duration and are designed to offer intensive postgraduate instruction. "Rotating" services are much more frequently offered than the straight "medical", or "surgical" and are planned to give the student a bird's-eye view of his profession. The typical "rotating" service, for example, is too short. In two years' time or less it attempts to include a period of work in surgery, medicine, obstetrics, eye, ear, nose and throat diseases, and often in neurology, pediatrics and dermatology as well. The straight "medical", "surgical", or "special" services offer in about the same time interval a period of more concentrated training in one or the other more general or special branches of the profession.

Many factors play a part in determining good or mediocre internships. One very striking feature is the great variability in the number of hospital beds per intern. Several hospitals are understaffed and expect their interns to cover more than fifty beds per man, while at the other end of the list are two so arranged that they have an intern for each eleven beds. It seems far to assume that no intern can cover satisfactorily more than about thirty beds, if he is asked to do more than this he cannot receive a very good training.

In order to show certain of the most noteworthy differences between hospitals which attract good and mediocre intern material comparative data have been tabulated from four hospitals of somewhat similar size, the first two affording the best type of medical or surgical training,

*Presented before the New England Hospital Association at Boston February 17, 1934.

ference, 68 per cent cures in the former and 72 per cent in the latter. The period required for relief of symptoms varied from a few weeks in two instances to a maximum period of seven years, with no consistent difference in the three groups in time required from beginning of treatment to cure. In the majority of individuals relief from symptoms was obtained in from six months to one year, a far longer time than is now usually required for cure by subtotal thyroidectomy in the iodized patient. The methods employed in the years studied are shown to have given good results after a period of not less than nine years, but each method entailed a longer period of treatment than do present methods.

FLAT FOOT

An Anatomical Reconstruction

BY FREDERICK JAY COTTON, M.D.,* AND GORDON MACKAY MORRISON, M.D.*

THE vast majority of flat feet call for no operation.

Many flat feet involve bony change, these cannot be "reconstructed" in any literal sense, must be operated on if need be by wedge operations, etc. But in others in which in Brack-

OPERATION FOR FLAT FOOT

Upper figure Shows the open astragalo-scapoid joint—the cut (a) above the supporting ligament carried forward across bones and articulations.

Lower figure The foot corrected the bone-ligament flap carried forward. The rear end of the scaphoid in the graft (b) the scapho-cuneiform articulation (c) the cuneiform metatarsal (d) are all carried forward one-half inch—and the whole strip pegged in place.

ett's phrase "the bony architecture is unchanged" one can reconstruct. Among these is a type often seen in young men in which a long lax foot, pronated flat, shows perfectly evident relaxation of ligaments not presaging much chance of correction by exercise. Only in such cases is this operation to be considered. It rests on the fact that the weight is transmitted from the top of the astragalus through its downward rotated head to the supporting calcaneo-scapoid ligament, a very definite and very strong structure even when relaxed. The operation consists in transferring the scaphoid at-

tachment of the ligament farther forward so as to tighten up the ligamentous support. The technique is shown in the accompanying cut.

The astragalo-scapoid joint is opened and a rather broad, thin osteotome, pointing outward and about 35 degrees downward, is driven through to the plantar surface of the bone, separating (roughly) one quarter of the scaphoid.

The line of the cut is continued forward, disregarding joint intervals, to $\frac{3}{4}$ inch in front of the base of the first metatarsal.

If then the foot is corrected into proper position in the direction of cavo-varus, then the bony flap, containing parts of scaphoid, of internal cuneiform and of metatarsal base, is easily slid forward to a new hold. The bony flap is loosened, never dug out of its bed on the under side.

The front end, the metatarsal piece, may be trimmed off as superfluous, and the main flap is to be pinned in its new place with small ivory or bone pegs.

CASE

J D (man now 27 years old), operated on at the Boston City Hospital in 1920, was examined in July, 1933. One foot only had been operated on (with expectation of doing the other after an interval). Thirteen years after, it showed a foot perfectly normal in stance and mobility. The left foot still showed a lax flat foot of extreme type with troublesome weakness.

In a very few other cases treated the result was good, but none other followed up for a long time.

The operation in no way interferes with lateral rotary motion in the subastragaloid joint. The only drawback is the need of waiting for solid bony union before unrestricted unsupported weight-bearing is resumed.

This operation is applicable to only a small selected group of cases, it is only one of many corrective measures for the relief of flat foot.

*For records and addresses of authors see page 817 issue of April 1st 1934.

teacher, so that everything the intern does can be scrutinized and criticized. The number of necropsies should be increased, interns and visiting staff doing all in their power to study diagnosis and treatment by the method of clinical-pathological correlation. In too many hospitals the intern's work is haphazard and superficial. The self-taught intern does not acquire much useful knowledge, he needs to be drilled in the art of practice, an art that can only be mastered by hard work intelligently controlled.

The intern should be encouraged to grow and develop. He should be urged to take an active part in staff conferences and in other medical meetings held under the hospital's auspices. Hospitals and staff meetings should be conducted regularly and with a certain degree of formality. They should be run off on time and the intern should present the cases under discussion, learning to speak on his feet, without notes, and clearly and succinctly. Too often, at such meetings, the intern is made to sit on the side lines and do the listening. This is discouraging, especially, as almost invariably with a little coaching, he can learn to give a good account of himself.

Hospital Trustees must be educated to realize that a Teaching Hospital requires certain equipment in addition to first-rate wards, laboratories and operating rooms. There must be an enthusiastic, well-selected staff acting under good leadership. There must be a sufficient number of interns in proportion to the number of beds so that each intern may have a chance to think and work at something out of his routine. There must be a suitable place for medical meetings and this room should contain apparatus for demonstrating charts, x-ray films or pathological specimens. There must be a library in the hospital, readily accessible to the interns and staff, and it should receive sufficient endowment to enable it to purchase up-to-date textbooks, as they are published, and to subscribe to the more useful medical journals.

The intern should be encouraged to write Medical writing, if it does nothing else, stimulates a beginner to wish to use a library properly, teaches him to read, analyze, criticize or abstract literature, and also something of facility of expression and of the difficulties of composition—all good things for a young doctor's development. The Allegheny County Medical Society of Pennsylvania has initiated an important experiment along this line by offering an annual prize of \$50 for the best case report submitted by interns of any approved hospital in the County. It would be a fine stimulus if the Massachusetts Medical Society were to offer a similar prize each year for the best case report written by an intern holding any of the Massachusetts rotating appointments. The chance to win such a prize might prove very inspiring.

The difference between good and bad intern training is not easy to analyze, since so much depends upon personalities. One fact, however, is very clear. The pace at which a hospital works and the quality of what it accomplishes depend on coöperation of the Staff, Trustees and Superintendent. These three bodies must understand each other's problems and must act in harmony. To admit that a hospital which trains interns is a Teaching Hospital, is a long step forward, for a Teaching Hospital has certain ideals and responsibilities which differentiate it sharply from an institution in which there is no teaching. The best organization of a Teaching Hospital differs in each community and requires careful consideration. Certainly no single plan of organization can be generally successful. The quality of the interns of Massachusetts can be improved and they can be given better training if the staffs, trustees and superintendents of our hospitals are interested to improve the medical education of interns and are willing to take an active part in advancing this aspect of their hospital's functions.

MORTALITY RATES

Telegraphic returns from 86 cities with a total population of thirty seven millions for the week ending April 7 indicate a mortality rate of 12.6 as against a rate of 11.6 for the corresponding week of last year. The highest rate (20.1) appears for Trenton N. J. and Wilmington Del., and the lowest (3.6) for Yonkers N. Y. The highest infant mortality rate (16.1) appears for Duluth Minn. and the lowest for Bridgeport, Conn. Knoxville Tenn., Lynn, Mass. Somerville Mass., South Bend Ind. and Yonkers, N. Y. which reported no infant mortality.

The annual rate for 86 cities is 12.7 for the fourteen weeks of 1934 as against a rate of 12.2 for the corresponding period of the previous year.

SUMMARY OF DEATHS AND DEATH RATES (ANNUAL BASIS) FROM AUTOMOBILE ACCIDENTS PER 100,000 ESTIMATED POPULATION FOR 86 CITIES FOR CORRESPONDING PERIODS OF 1934 AND 1933

	Week ending		First 14 Weeks	
	April 7 1934	April 8 1933	1934	1933
Total deaths	173	138	2,227	1,962
Deathrate	24.1	19.2	22.2	19.5

and the other two a "rotating" training less valuable

It is evident, on the whole, that the better scholars—and by and large they make the better interns—tend to concentrate in comfortably endowed hospitals where there is a resident staff large enough to carry forward a satisfactory type of clinical work, and in institutions where the percentage of necropsies is high. This fig-

time during their period of service. The amount of intra-mural illness should be kept as low as possible and this can only be accomplished by proper care of the personnel.

The Council on Hospitals and Medical Education of the American Medical Association approves of a "rotating" internship as an essential for a hospital to be approved for intern training. If young doctors are best initiated in

FIGURE 1

ure has come to be generally recognized as a fair index of the educational activities of a hospital.

HOW TO IMPROVE MASSACHUSETTS INTERNSHIPS

Massachusetts is in a position to improve her internships. There are many well-equipped hospitals, and excellent intern material is at hand each year. The problem is to develop these hospitals as centers of postgraduate education to better advantage, and to improve their general average of intern training.

Each hospital which has placed itself on record as being capable of training interns must recognize that in so doing it has assumed all the responsibilities of a Teaching Hospital. The Staff, Trustees, and Superintendent must admit this fact and must cooperate to improve the opportunities for their house-pupils to receive adequate and proper instructional facilities.

No intern should be appointed who is not a graduate of a medical college recognized by the Massachusetts Medical Society. No intern should be appointed without a personal interview and preferably should receive some sort of an examination regarding his abilities before he is accepted. The intern's quarters should be attractive, his food good, and he should have adequate facilities for rest, privacy, study and recreation. It has been pointed out that in one Massachusetts Hospital about a third of the interns enter the institution as patients at some

to practice by this kind of hospital experience, "rotating" internships must be made more desirable. At present, in Massachusetts, they are not greatly sought after. An appreciably poorer type of student is trained in hospitals offering this kind of internship than in those offering only "medical" or "surgical" services. In order to improve this state of affairs, the teaching in these hospitals must be conducted with especial care.

THE HOSPITAL AS A TEACHING CENTER

Staff, Trustees and Superintendents of hospitals with "rotating" interns should work together more purposefully to organize the best possible kind of intern teaching. For example, in every hospital a carefully considered and well-planned intern curriculum should be developed by an appropriate committee, certain staff members, especially if they have a bent for teaching, should be delegated to see to it that the intern's work is checked up, that his records are up-to-date and well and carefully written, that his routine laboratory and clinical work is properly done, that his physical examinations as recorded are accurate, that diagnoses are made correctly and that treatment is carried out properly and systematically. A visit with the intern should be made each day to each of the intern's patients by a competent member of the Visiting Staff, unhurriedly and as a

230/150 He remained in a semistuporous condition throughout that day, groaning continually On the following day however he was quite comfortable and quiet and was even allowed one cigarette His mind was clear

The day after this upon his request he was given a bedpan Five minutes later he was found breathing noisily, with his right eye closed, a blood pressure of about 125/100 and a very weak pulse He could not be aroused All his limbs were flaccid, but reflexes were obtained on both sides About fifteen minutes later he became very evanotic and in spite of artificial respiration died

DIFFERENTIAL DIAGNOSIS

DR TRACY J PUTNAM A man who is substantially healthy has two acute episodes one mild one, followed in three weeks' time by one which renders him unconscious I think our first thought on hearing the history to that extent is that the patient has had a cerebrovascular accident of some kind Perhaps the first thing to think of is that he had a thrombosis which later gave rise to a hemorrhage, a thing which we know often happens, although I think the three week interval is rather unusually long As we look over the precise symptoms that he had, however, that possibility becomes somewhat less probable and I think we can find a good many manifestations that can be explained better on a basis of subarachnoid hemorrhage than of hemorrhage within the cerebral substance In the first place pain in the back of the neck and headache are rather unusual with thrombosis That is apt to come on painlessly Another thing is the blood pressure We expect the blood pressure to come down following thrombosis or hemorrhage within the cerebral substance The mental perturbation is perhaps not very specific of one thing or another

Of course the onset of an accident in the bathroom is a very common manifestation

I think the past history adds nothing, at least the findings are not very germane to the situation here Nor is the neurologic examination very important, except that there are mild signs of meningeal involvement, specifically the difficulty in carrying out the Kernig test

I should like to call attention again to the persistent high blood pressure, which would certainly be unusual if this were the ordinary type of cerebral hemorrhage So is the spinal fluid when we come to that The fluid was grossly bloody, with an initial pressure of 300 and over a million and a half red cells That is an extremely bloody fluid of course, almost one third pure blood It would be very unusual for a man to have a massive hemorrhage deep in the substance of the brain and have enough of this hemorrhage leak into the spinal fluid to give him such a high cell count and for him to sur-

vive as long as this patient did Moreover, on centrifuging the fluid was seen to be xanthochromic, which is definite evidence of course that the hemorrhage has existed for some time That raises the presumption that it came on three weeks earlier I should like to call your attention to the fact that there were twelve hundred white cells, which again is evidence of long-continued irritation of the meninges from the presence of red cells in the fluid

The pressure apparently came down and so did the count of red cells, although the number of white cells increased This is what we should expect with a gradually improving subarachnoid hemorrhage

An interesting point is that we do not expect to find arteriosclerosis as an etiological factor in the ordinary type of subarachnoid hemorrhage Subarachnoid hemorrhage by and large is a disease of young people rather than of arteriosclerotic people I do not suppose, however, that the presence of arteriosclerosis will prevent subarachnoid hemorrhage, and it is quite possible that this patient has a congenital aneurysm, which is the ordinary cause in addition to arteriosclerosis

The terminal event I think is quite obviously a recurrence of the original hemorrhage, and once more it comes on with pain The neurologic findings are not adequate, it seems to me, to permit us to localize the site of origin of this hemorrhage The record is rather noncommittal on this occasion, although of course we know from experience that aneurysms are most apt to be in the circle of Willis or one of its branches Perhaps if we wanted to be very accurate about it we might say that the pain behind the left eye suggests that the aneurysm was on the left and that the pain was due to pressure on the sensitive meninges about the sinuses On the other hand it is a little hard to explain why his right eye should be closed under these circumstances at a later attack.

To sum up, this man obviously has arteriosclerosis with a high blood pressure, and we should expect to find evidence of that in the brain He also evidently has a subarachnoid hemorrhage It is difficult to be sure that he has not a certain amount of intracerebral hemorrhage, but that seems unlikely It seems more probable that he has a combination of congenital aneurysm with arteriosclerosis.

CLINICAL DIAGNOSIS

Subarachnoid hemorrhage

ANATOMIC DIAGNOSES

Subarachnoid hemorrhage

Ruptured aneurysm of anterior communicating artery

Probable rupture of left middle cerebral artery

Duodenal ulcer, perforated

ANTE MORTEM AND POST MORTEM RECORDS AS USED
IN WEEKLY CLINICAL PATHOLOGIC EXERCISES

EDITED BY RICHARD C CABOT, M.D.
F M PAINTER, A.B., ASSISTANT EDITOR

CASE 20171

PRESENTATION OF CASE

This is the case of a forty-two year old American

Three weeks before admission while talking with a friend everything became dark and he thought he was going to faint. At the same time he had severe pain in the back of his neck and the left side of his head. Following the attack this pain was present intermittently until admission. For a few days after the onset of the pain he also complained of stiffness of his neck and of the calves of his legs. He was told by his doctor that he had a blood pressure of 230. The patient refused hospitalization at that time. He remained at home most of the time, was very apprehensive, and insisted that his wife be with him all the time. He complained of peculiar feelings and noises in his head. On the morning of admission he informed his wife that he was about to take an enema. Some time later she heard him call to her from the bathroom. She was sure that he did not fall down because she was in the next room and had heard no noise. When the patient was found he was lying on the floor unconscious, his body limp and his eyes set. A physician gave him a stimulant which revived him for a while. He then became very noisy and violent, but was finally quieted with a sedative. There is no history of any visual disturbance, fever, cough or pain in the chest during the three weeks preceding admission.

His mother died of cancer of the uterus, his father of angina. Two sisters were living and well. A third had died of pulmonary tuberculosis.

He had been married eighteen years. His wife and two children were living and well. There had been no miscarriages.

Ten years before admission he had been at a hospital where a diagnosis of gastric or duodenal ulcer was made. Operation was advised but was refused. Four years before admission at another hospital a diagnosis of gastric ulcer was made. He was put on a diet, but did not adhere to it very conscientiously. He had no severe bleeding.

Physical examination showed a thin semistuporous man. The left pupil was oval in shape. Both fundi showed redness and hazy disks. There was slight choking of the disks,

probably one diopter, and slight nicking of the veins, with some tortuosity of the vessels. There was some stiffness of the neck, not marked. The heart was not enlarged. The blood pressure was 202/120. When a Kernig test was attempted he complained of pain in his hamstrings. He was clear mentally, but his memory for recent events was poor. He was quite irritable and very noisy. He had difficulty in choosing words and sometimes used the wrong word to express himself. There were no uncinate attacks. Examination of all his cranial nerves was negative. His reflexes were all active on both sides. There was a slightly positive Kernig on both sides. The biceps, triceps and knee jerks were slightly hyperactive. The Babinski was negative, but from his history it was said to have been positive on both sides one week before entry.

The temperature was 98.8°, the pulse 52, the respiratory rate 11.

Examination of the urine was negative. Examination of the blood showed a red cell count of 4,800,000. The hemoglobin was 75 per cent. The white cell count was 15,500, with 82 per cent polymorphonuclears. A Hinton test on the blood was negative. The blood sugar was 98 milligrams, the non-protein nitrogen 29.

A lumbar puncture showed grossly bloody fluid. Pulse and respiratory oscillations were normal. The initial pressure was 300, after removal of 5 cubic centimeters of fluid it went down very slowly to 245. The cell count showed 1,500,000 red blood cells and 1200 white blood cells. The fluid was xanthochromic in the centrifuged specimen. The Wassermann was negative. A second lumbar puncture done three days after the first showed grossly bloody fluid and an initial pressure of 120. About 8 cubic centimeters of fluid was removed, at which time the pressure was 60. A cell count showed 62,000 red blood cells and 600 white blood cells. The centrifuged specimen was definitely xanthochromic. The total protein was 126, the sugar 38.2, and the colloidal gold 111222100. A third lumbar puncture done three days later showed cloudy yellow fluid. The initial pressure was 280. After the removal of 16 cubic centimeters the pressure went down to 140. The cell count showed 1760 crenated red blood cells, 320 polymorphonuclears and 320 lymphocytes. An alcohol test was positive. The ammonium sulphate test was negative. The total protein was 101, the colloidal gold 0122210000. The centrifuged specimen showed a scanty red sediment with xanthochromic fluid above.

On his twelfth day in this hospital the patient suddenly cried out, complained of pain behind his left eye and lapsed into stupor. Examination showed stiffness of the left arm and leg and flaccidity on the right. The deep reflexes were symmetrical but very weak. Bilateral Babinski was present. The blood pressure, which had been about 180/120, was now

X-ray examination of the heart showed enlargement, the transverse diameter measuring 18.3 centimeters, 15 to the left and 3.3 to the right. The transverse diameter of the chest measured 30 centimeters. There was marked prominence of the left ventricle. The supracardiac shadow was considerably increased in the anteroposterior view. In the lateral view however the aorta appeared of normal size.

He was put on digitalis and got good diuresis. Nine days after admission his temperature rose to 103.2° and that evening to 104°. There was questionable slight dullness at the right base. He showed slight anorexia and the digitalis was omitted. The following day there were many dull moist râles at the right base, with coarse moist rhonchi. The sputum that morning was rusty and pneumococcus type II was obtained from it. X-ray examination of the chest at this time showed extensive mottled dullness involving the lower two thirds of the right lung field. The dullness was more intense in the midportion of the chest. The upper portion of the right lung field and the entire left lung field were clear. The patient two beds away had a type II pneumonia and it was believed that a cross infection had occurred. Two days after the onset of the rise in temperature he was given serum after a negative eye test and a questionable skin test. The first 5 cubic centimeters was given without reaction, but after 7 cubic centimeters of the 25 cubic centimeter dose was injected he felt weak and began to sweat. His pulse became poor and his blood pressure went down to 70/50. The injection was stopped. After ten drops of adrenalin his blood pressure rose to 130/90. He was desensitized without any reaction. He became slightly cyanotic and was put into an oxygen tent. His temperature remained elevated, reaching 104.2°. The day following the serum treatment his pulse became rather small rate 140 and he was moderately cyanotic. His white blood cell count which had been 20,900 at the onset of the pneumonia dropped to 4,000. His blood pressure steadily failed and he died that day, three days after the onset of the pneumonia.

DIFFERENTIAL DIAGNOSIS

DR. F. DENNETTE ADAMS. The history is one of cardiac failure of the congestive type beginning three years before the final break and gradually becoming worse. The cough was doubtless due to mild congestion of the lungs.

There are these possible etiologic factors: rheumatic, syphilitic and hypertensive-arteriosclerotic heart disease. There is nothing in the history pointing toward a rheumatic background and no murmurs are mentioned in the physical examination, so rheumatic disease can readily be excluded.

The cardiac break began at forty which is within the age zone of syphilitic heart failure.

Against the likelihood of this disease, however, is the interval of three years between the onset of the first symptoms and of the final break. The characteristic murmurs are also absent. The x-ray observation of widening of the arch would suggest syphilis, but the normal appearance in the lateral plate offsets the evidence obtained by the anteroposterior view.

The man had hypertension before he came into the hospital, with a pressure doubtless higher than the reading of 155/130 recorded at the time of admission, which was after the failure had become well advanced. It is safe to assume that we are dealing primarily with a case of hypertensive heart disease with failure.

Whether angina pectoris, coronary disease, or coronary occlusion was present it is impossible to determine from the facts given in the history. The chief complaint is recorded as pain in the chest of three weeks' duration, but the account given in the history of the present illness stresses shortness of breath and also a dull aching substernal pain aggravated by exercise. It is important to know more about the pain, its degree, type and character of onset, before any conclusions concerning coronary disease can justifiably be drawn.

The electrocardiogram in this instance is of little help. An electrocardiogram showing a low T wave, if taken shortly after admission, might point toward coronary change, but if taken two or three days later and presumably following digitalis therapy, the low or flattened T wave loses its value as a diagnostic aid.

Certainly the kidneys are not appreciably involved.

The abdominal swelling makes one suspicious of moderate ascites. Apparently the physician who performed the physical examination suspected the possibility of its presence, but the evidence is not convincing. It is likely that the feeling of distention of which the patient complained was caused by congestion of the liver, occurring fairly suddenly along with the other manifestations of the acute break. I do not believe that ascites is present.

The barrel chest suggests emphysema. Nothing is recorded about lung signs and nothing reported in the x-ray about emphysema. There is one other fact which also points toward this possibility, namely that the left side of the heart and the width of the arch were found greater by x-ray than by percussion. These are rather indirect bits of evidence, but of some significance nevertheless.

The acute infection must have been pneumonia, doubtless a cross infection from the other patient. We know that such occurrences are not rare. Here we have a splendid example of the need for isolation of pneumonia patients, an ideal procedure difficult to carry out in any general hospital. Bronchopneumonia is rare with type I or II pneumococcus, lobar pneumonia almost a certainty. The mottling seen by

General peritonitis
Emphysema, bilateral apical
Cervical rib, bilateral
Arteriosclerosis

PATHOLOGIC DISCUSSION

DR TRACY B. MALLORY The autopsy on this man showed outside the head two entirely unexpected findings. The final attack of coma and death may in fact have had nothing whatever to do with his cerebral pathology. You remember that far back in the past history he had had a diagnosis of ulcer of the stomach. That ulcer turned out to be in the duodenum rather than the stomach. It had perforated and he had a general peritonitis. That is of some interest in connection with Dr. Cushing's theory of the activation of stomach ulcers by certain brain lesions.

The other rather unusual finding of absolutely no significance in his illness was a bilateral emphysema of both apices of the lungs. This was very sharply localized, just at the apices, and on examining the thoracic cavity it was evident that the apices of the thoracic cavity were unusually high, probably due to bilateral cervical ribs. I made this cast of it. He had approximately three times as much lung above his clavicle as the average person, and the emphysema on each side was absolutely localized to that area. The bronchi leading to these areas were normal or slightly dilated, certainly not obstructed. The remainder of the lungs showed no emphysema whatever.

The cerebral findings come much closer to Dr. Putnam's prediction.

DR CHARLES S. KUBIK On examination, the brain showed only a moderate amount of blood in the subarachnoid space. On the inferior surface of the optic chiasm there was a mass one centimeter in diameter consisting of partly organized clotted blood which obviously had come from a ruptured aneurysm of the anterior communicating artery. This was a thin-walled affair about two millimeters in diameter. No aneurysms of any of the other cerebral arteries were found. There was a moderate degree of arteriosclerosis.

Aneurysms such as this, in or near the circle of Willis, are found in most cases of spontaneous subarachnoid hemorrhage. The subjects are usually young people without arteriosclerosis or hypertension and without history or other evidences of syphilis. The aneurysms, or a majority of them, are probably the result of a congenital defect in the muscularis. It is thought that infected emboli coming from an endocarditis may account for some of them. In the case before us the wall of the aneurysm was not sclerotic, and I should suppose that here too there was probably congenital weakness of the vessel wall, with hypertension as an additional factor.

DR MALLORY I neglected to mention that throughout the body there was a diffuse arteriolar sclerosis, which one would expect with a long-standing hypertension.

CASE 20172

PRESENTATION OF CASE

A forty-three year old French weaver entered complaining of pain in his chest of three weeks' duration.

A year and a half before admission he first noticed dyspnea and cough, worse on exertion. The dyspnea disappeared after a few weeks, but the cough still dragged on. He was comparatively well until three weeks before admission, when marked dyspnea on exertion appeared again. This was associated with cough and blood-stained sputum. He had one or two sharp attacks of orthopnea. He had to sleep on two pillows. He also experienced a dull aching substernal pain, aggravated by exercise. One week before admission he noticed swelling of his abdomen.

His family and marital histories are irrelevant.

Two months and a half before entry he had all his teeth removed.

Physical examination showed a well developed and nourished man propped up in bed. There was slight cyanosis of the lips. His chest was barrel shaped. The heart was markedly enlarged to the left, measuring 11.5 centimeters from the midsternal line in the fifth interspace. The supracardiac dullness measured six centimeters. The pulse was small, thready, and almost impossible to feel. The blood pressure was 155/130. There were râles at both bases. The liver edge was sharp, smooth, tender, and palpable four fingerbreadths below the costal margin. There was a large right scrotal hernia and a healed herniotomy scar on the left. There was slight fullness of the flanks with questionable shifting dullness and questionable fluid wave.

The temperature was 98.6°, the pulse 100. The respirations were 20.

Examination of the urine showed a specific gravity of 1.010 to 1.022 and a slight trace of albumin. The sediment showed occasional hyaline casts and a rare white blood cell. Examination of the blood showed a red cell count of 5,680,000 and a hemoglobin of 70 per cent. The white cell count was 8500, with 70 per cent polymorphonuclears. The stools were negative. Hinton and Wassermann tests were negative. The non-protein nitrogen was 33 milligrams. A phenolsulphonphthalein test showed 68 per cent secretion at the end of one hour, 33 per cent of which was excreted in the first fifteen minutes.

An electrocardiogram showed normal rhythm, rate 105, slightly widened Q R S waves, flat T₁ and T₂, and slight left axis deviation.

larger volume than 0.02 cc is introduced the initial elevation is, of course, correspondingly larger. In judging the test, it is important to note the behavior of the inoculated region at frequent intervals and to regard as a positive reaction the rapid transformation of the small white elevation into a genuine urticarial wheal with a surrounding zone of erythema. The result of the skin test in this patient is probably negative.

The results of the skin test with normal horse serum diluted 1:10 with normal saline are difficult to judge on account of the occurrence of doubtful reactions and this difficulty is enhanced with Felton's antibody diluted 1:10 with 1.5 per cent salt solution. Confusing results with skin tests have led to the substitution of the less delicate ophthalmic test, but it is undesirable, I think, to abandon the skin test entirely and it is well for us to continue to use it here as an additional safeguard in connection with the history and the ophthalmic test.

Patients with obviously positive skin tests should not, I think, be treated with antipneumococcic serum. In patients with histories negative for hypersensitiveness and negative ophthalmic tests, but with doubtful skin tests it is safer to proceed cautiously, starting with very small doses subcutaneously, i.e., from 0.005 to 0.025 cc and doubling the dose every half hour until 1.0 cc is given. Following this, 0.1 cc diluted with normal saline may be given intravenously and the intravenous dose doubled every half hour until the required amount is given.

It is stated that the patient had sweating, weakness and low blood pressure after the injection of serum. In our experience about ten per cent of serum-treated patients have had a transient complex of symptoms usually immediately after the first dose including some shortness of breath, cyanosis, rapidity of the pulse, thoracic oppression and apprehension and I would not regard the reaction this patient had as dangerous. It is not unusual to have a low blood pressure at the inception of a severe acute infection. I myself, when I had lobar pneumonia, had a blood pressure of 90/60 for the first twenty-four to thirty-six hours. It is not necessary to stop the use of serum under these circumstances. The subsequent injection of 45.0 cc without trouble in this patient supports this point of view.

With respect to the merits of antipneumococcus serum in the treatment of type II pneumococcus pneumonia, analysis of the available evidence indicates that the usual mortality of type II is about 40 per cent and that serum has reduced the mortality to 30 per cent, and in early treated patients it is fair to assume that that mortality might be reduced to below 30 per cent. In the State project there have been eighty-four patients treated within the first four days of the illness with twenty-four deaths, a mortality of twenty-nine per cent.

DR. PAUL D. WHITE: I think that Dr. Adams has covered very well the cardiac side of the case and the rest of it too. The difficulty of determining clearly whether there was coronary disease from the history given is great. One would want a much more adequate story than Dr. Adams had to work on.

DR. MALLORY: Do you think the presence of cardiac decompensation influenced the reaction to the serum in any way?

DR. WHITE: I do not know. I suppose that anyone who has been through such an illness (congestive failure) as this patient had would be much less likely to recover from a second illness such as pneumonia.

DR. J. H. MEANS: I wanted to ask Dr. Lord much the same question,—whether in the face of congestive failure, such as this man had, it was desirable to give serum at all, or whether cardiac failure constitutes a contraindication?

DR. LORD: I would not say it constituted a contraindication in this case, as it is difficult to judge from the description just how ill this patient was. Estimate of the seriousness of illness depends largely on the aspect of the patient and is difficult to put into writing. I would in general say, however, that I think that patients who are already desperately ill and in extremis should not be treated with antiserum. The question then may quite naturally be raised whether statistical studies based on serum-treated cases with the exclusion of the desperately ill compared with a control group not so treated are reliable. In answer to that I would say that observation of this precaution would inevitably introduce a source of error into the figures when no account was taken of the day of the disease in which serum treatment was begun. But the mortality of cases treated with serum within the first few days of the illness is probably not modified to any significant degree, because patients with pneumonia are rarely desperately ill during this early period.

DR. ADAMS: May I add one statement? It seems to me in connection with the changes during the serum reaction that the significant fact is not that the blood pressure dropped to 70/50 but that it dropped from 150/130 down to 70/50. Such a change, particularly in the diastolic figure, is certainly an indication of marked vasomotor upset.

DR. ALFRED KRANES: The blood pressure was not taken immediately before the serum was given. That reading, 150/130, was the admission blood pressure.

DR. ADAMS: I think it is safe to assume that if the pressure was 150/130 when he was admitted and if he improved under treatment, his blood pressure probably did not go down until after the onset of the pneumonia, and that even then it would not have failed so appreciably during the early stages of this complication. One associates such a fall with the final stages of the disease.

x-ray is not at all inconsistent with the early stages. Whether he had involvement of the lower lobe or of the lower and middle lobes is difficult to decide. The fact that the greatest density by x-ray was in midchest points toward middle lobe rather than lower lobe, although nothing is recorded concerning the straight, clean-cut line which is usually seen by x-ray with middle lobe consolidation.

I admire the courage but question the wisdom of those who continued to give serum after they had encountered trouble once. I have no desire to appear too critical or too much of a reactionary, but I think I am justified in making the statement that type II serum has by no means been universally accepted as a therapeutic agent of proved merit, and that discontinuance of its administration after one severe serum reaction might have been a wiser course. We do not know that such a serum reaction does not have a detrimental effect on the patient in spite of recovery from the immediate symptoms. On the other hand, there are two sides to the problem, and those who have faith in the efficacy of type II serum therapy are justified in using it. Had the pneumonia been of type I origin the problem would have been different, for type I serum administered early is generally accepted as a therapeutic agent of some value. But it is none the less my conviction that some of the enthusiasm for serum therapy is not justified by any results which have thus far been demonstrated in connection with its use, and that its disadvantages are being minimized while its advantages are sometimes overstressed.

I should be interested to know if the patient had a positive blood culture. I always expect it in a sick pneumonia patient with a low white cell count.

DR. TRACY B. MALLORY: There were no positive cultures during life.

DR. ADAMS: My diagnoses in this case are Hypertensive and arteriosclerotic heart disease with congestive failure.

Possible coronary disease.

Lobar pneumonia of the right lower lobe, possibly of the right middle lobe.

Possible pneumococcus septicemia.

CLINICAL DISCUSSION

DR. FREDERICK T. LORD: There seems little question in respect to the nature of his pneumonic process, and I would agree that the finding of type II in the sputum in a patient with a complex of symptoms consistent with pneumonia is almost certain evidence of lobar pneumonia.

With respect to contagion, in Smilie's epidemiologic studies he finds that Types I and II pneumococci occur in family contacts in a percentage of about twenty per cent, but it is by no means certain how pneumonia arises under such circumstances. The frequency with which lobar

pneumonia is preceded by a "cold" is perhaps significant in this connection, and it may be that there is a relationship between the filtrable virus concerned in the etiology of the "cold" and the pneumococci which cause pneumonia. Dochez's studies on the acute infections of the respiratory tract suggest that the filtrable virus which initiates the primary infection promotes secondary bacterial infection and the spread of the secondary invaders to contacts. In Smilie's studies contact alone does not seem an adequate explanation and the large proportion of those suffering from acute "colds" among carriers of homologous pneumococci in family contacts suggests that family epidemics of "colds" may determine the transfer of types I and II pneumococci from infected to uninfected individuals.

Smilie's findings suggest that there is little danger of contagion among patients or the staff in hospitals. The incidence of homologous pneumococci among contacts in hospitals is about two per cent in contrast to about twenty per cent in family contacts. The presence of a patient with type II pneumococcus pneumonia two beds away from this patient is hardly enough to prove contagion from one to the other, although, of course, one cannot deny it.

There is one aspect of this case especially deserving of comment, and that is that the pneumonia developed under observation in the hospital, and this affords an unusual opportunity to note the behavior of the temperature. In a few instances in which a type I or type II pneumococcus pneumonia has developed under such circumstances there has been a very rapid elevation of temperature from normal to its maximum within the space of only a few hours, and in this patient the temperature rose from normal to 103° within a period of about four hours. In addition, the patient had a cough and bloody sputum, but the initial manifestations were atypical in the absence of chill and stitch in the side. An explosive onset and the grouping of initial symptoms are usually sufficient to suggest lobar pneumonia, but atypical features here and the presence of cardiac disease probably made the early diagnosis uncertain. An unusual opportunity is, of course, afforded for early treatment under these circumstances, and yet the diagnosis of type was not made until the day after the onset and serum was not given until the following day. This seems an unjustifiable delay if we plan to treat type II pneumococcus pneumonia with serum.

Another aspect of this problem is the result of the tests for hypersensitiveness to horse serum. The ophthalmic test was negative, but on the application of the intradermal skin test there was a wheal one centimeter in diameter without surrounding erythema. The introduction of 0.02 cc of a 1:10 dilution of normal horse serum into the skin produces a white elevation only a few millimeters in diameter. If a

AUTONOMIC REPRESENTATION IN THE CEREBRUM

It has long been recognized, since the time of Rokitsansky, that the gastro-intestinal tract may be modified pathologically by lesions in the brain. Ulcerations, particularly of the stomach, have occurred in a sufficient number of cases of brain tumor to lead to a neurogenic conception of peptic ulcer. At first the responsibility for this process was placed upon the peripheral vagus nerve, later it was thought the center might be in the medulla, then in the mid-brain, and finally it is now recognized by Cushing and others that a lesion of the interbrain may lead to erosions and even acute perforations of the esophagus, stomach or duodenum. It would seem at this level, at least, that there is a station for vegetative impulses that are easily affected by psychic influences, and although this theory, mainly put forward in recent years by Cushing, does not, perhaps, account for all ul-

cerative processes, it appears to be a reasonable explanation for the majority of them.*

The work which has led to these conclusions has been partly from the clinic and partly from the physiological laboratories. From the latter source a new conception of one of the causative factors in another intestinal disorder, namely, intussusception is discussed in this issue of the *Journal*†. The work has been done in a large series of monkeys in which the motility of the gastro-intestinal tract has been studied in relation to various operations on the cerebral cortex. The area of the brain operation, which was followed by spontaneous intussusception and death in three otherwise healthy monkeys, was a small region in front of the motor cortex now referred to as the "premotor area." This region appears to contain autonomic representation for the gastro-intestinal tract and probably includes both excitatory and inhibitory components.

The work referred to above, on intussusception, is another step in advance in the neurogenic theory of gastro-intestinal disease, the clinical implications of which must be considered as far-reaching. Intussusception in children is by no means a unique disease and is, in most cases, a dangerous cause of intestinal obstruction. If it is sometimes due to cortical dysfunction, as indicated by animal experimentation, a new conception of the subject is at once presented which should lead to further investigation of this important topic.

THE USES OF ADVERSITY

WHEN the Senior Duke of Burgundy, self-exiled in the Forest of Arden, remarked that the uses of adversity are sweet, he was probably using "uses" in its Elizabethan sense of customs or practices. It is not so much the advantages or benefits which men may derive from adversity which are valuable, as the activities and occupations to which they turn, neglected in the piping times of prosperity. Thus, "as from the nettle danger we pluck the flower safely," so from the toad of adversity "ugly and venomous," we may pluck the precious jewel which he is fabled to wear in his head, and which is proof against all other poisons. The modern parallel of this parable of the Duke's is the spirited strip in one of our esteemed and familiar comic contemporaries, entitled, "What to do with the Wolf at the Door."

In common with all his fellow men in this America of the past four years, the doctor has come in for his share of adversity, though no mention has yet been made of any code for his

Adrenal adenoma

PATHOLOGIC DISCUSSION

DR. MALLORY On the epidemiologic side of the case, we see a considerable number of decompensated cardiacs who pick up in the last few days of their illness an acute bronchitis and sometimes a moderate degree of bronchopneumonia, usually type IV pneumococcus or

streptococcus. We do not very often see a true lobar pneumonia as a terminal incident in heart disease. Do you agree with me, Dr. White?

DR. WHITE Yes

DR. MALLORY So that the appearance of a type II lobar pneumonia must be considered an unusual event in a case of this sort. The fact that the patient in the next bed but one was suffering from the same disease is suggestive, but of course is not proof of contagion.

The autopsy showed entirely what was predicted except for the location of the pneumonia, which was in the upper lobe and not in the lower. Otherwise everything was as we expected.

DR. WHITE How much did the heart weigh?

DR. MALLORY Five hundred grams. The coronary arteries were entirely negative. The kidneys were practically normal in size. There is no question but that it was a pure hypertensive heart disease.

A PHYSICIAN Was there any emphysema?

DR. MALLORY No significant degree of it.

Massachusetts General Hospital His personality has endeared him to colleagues and patients alike

Boston and the Massachusetts General Hospital will regret his transfer to New York, but are glad that he has been offered this larger opportunity, and feel sure that he will repeat, on a greater scale, the success which he has attained in New England

MASSACHUSETTS LEGISLATIVE NOTES

THE VETO OF HOUSE BILL NO 1305*

The Governor vetoed House Bill 1305 which was designed to authorize the University of Massachusetts Incorporated to grant the Degree of Bachelor of Science The argument of His Excellency is so cogent that we submit it in full as follows

The Commonwealth of Massachusetts Executive Department Boston Massachusetts March 19 1934 To the Honorable Senate and House of Representatives

I am returning without my approval House Bill 1305 entitled An Act authorizing the University of Massachusetts Incorporated to grant the Degree of Bachelor of Science To recognize this university as eligible to grant the degree of Bachelor of Science holds out to the general public that courses of instruction are given the successful pursuit of which results in a graduate having attained the same scholastic standing as a graduate from the other Massachusetts institutions now granting the degree As a matter of fact there is no course of instruction at the University of Massachusetts Incorporated which furnishes the same instruction received by the recipient of a degree of Bachelor of Science graduating from any of the other institutions of learning now granting the degree This Commonwealth is asked to permit the awarding of a degree of Bachelor of Science in order that the University of Massachusetts Incorporated may set up a course of study in accordance with the recognized educational standards for the degree In other words Massachusetts is asked to grant the degree on faith that the institution will conform to recognized standards and, in my opinion the authority to grant degrees should not be conferred in that manner In any event an analysis of the assets educational and otherwise of this institution do (sic) not give sufficient assurance of a maintenance of the high standard which this degree requires to warrant

The record of the veto is as it appears in House Bill 1305

relief Happily, like his professional brethren the clergyman and the teacher, he is above the need of a code, or rather he has a code of his own which should fortify him against misfortune and afford ample occupational, if not financial, compensation for the unemployment which the chance of the times may have brought

The average doctor during the period of so-called depression has seen his practice and income diminish from three principal causes. First, many patients who otherwise would have consulted him, being now so reduced in material circumstances that they cannot afford to do so, go instead to free public clinics, where they obtain excellent advice, care, and service at little or no cost. The enormous recent growth in the clientele of public medical charitable institutions is evidence of this. Secondly, many of those patients who still consult their private physician rightly expect and demand that his fees shall be much lower than those which they paid willingly a decade ago. Thirdly, many patients fail to pay even the modest fees which the doctor charges, so that his collections fall far below the total of reduced bills which he renders. Thus the average doctor is left wondering how he shall meet his overhead, support his family, educate his children and pay the increased tax on his diminished income.

It is not our present purpose, even were we able to do so, to suggest means of meeting these problems. Rather we would turn attention to some of the "uses of adversity," some of the ways in which the doctor, after solving these problems for himself as best he can, may find occupational advantage for the increased leisure brought him by unemployment.

First, and highest of all, is the privilege which the doctor always enjoys of using his professional knowledge and skill for human service without thought of monetary return. It is the actual exercise of his craft, after all, which affords his greatest satisfaction, his beneficent contact with fellow beings which earns their gratitude and his own happiness.

Secondly, the doctor may find absorbing occupation for leisure, not professionally employed, in his own home and family, if he be fortunate enough to have them. It is characteristic of Americans that they must always go abroad for pleasure and relaxation. It was a successful calamity which first taught the ruined banker to appreciate his own wife and children. So the doctor, formerly so busy that he was never at home, may now learn to enjoy the companionship of his family, to discover what delightful people they really are, to become absorbed in studying astronomy or carpentering with John, in helping Mary with her French or history or music, or even to get out his long disused violin and join the family quartet, though it be as second fiddle. There are always plenty of domestic repair jobs which he can undertake

to the joy of his superior four fifths, and to which he can apply the intelligence and mechanical ingenuity which he has acquired in the fields of science. And in his garden, the original habitat and pleasure ground of the human race, he may find at once, healthful physical labor, aesthetic satisfaction, and perhaps even valuable supplement in produce to the *res angustae domi*.

Finally, it is in the study or by the fireside, that the doctor may find best occupation for his new-won leisure of adversity in reading, marking, and digesting inwardly, not only the medical journalism with which he always feels it his business to keep up, but also the better general literature which he usually neglects. One of the faults of our previously plethoric lives has been that we have let most of our books "rust unused," or rather unperused, on our shelves, so that we have been more familiar with their bindings than their contents. Either Cicero or Pliny, in one of his letters of advice to a young man, wisely and somewhat paradoxically remarks, "It is more important to read the books you own than to own the books you read." This is now the doctor's opportunity, to read the books he owns and thereby make them really his. In this respect our ancestors, with their scanty but well-read libraries, were often better off than we, with our unregarded abundance.

Perhaps we may venture farther hereafter on the subject of the doctor's library. For the present, suffice these suggestions as to some of the uses of adversity which he may find sweeter than at first he is ready to suspect. After all, most of our afflictions generally turn out to be disguised blessings which we have entertained unaware, and inexpensive pleasures prove often the most precious. If he doubt this, let the doctor turn his unoccupied hours to those studies which are at once, "the adornment of prosperity, the solace and refuge of adversity."

DOCTOR WILSON GOES TO NEW YORK

It is always gratifying to know that what we have is desired by others, but not so pleasing when we lose our most valued possessions to them. So it is with the acceptance by Dr. Philip Wilson of the position of Surgeon-in-Chief of the Hospital for Ruptured and Crippled in New York City.

In Boston, Doctor Wilson has made for himself an enviable reputation. With Doctor Cochrane, he has published a textbook on "Fractures and Dislocations" and he is the author of the section on Amputations in the Oxford System of Surgery. He has had the honor of being president of the newly formed American Academy of Orthopedic Surgery. He is an inspiring teacher and has been a productive and skillful member of the Orthopedic Department at the

Massachusetts General Hospital His personality has endeared him to colleagues and patients alike

Boston and the Massachusetts General Hospital will regret his transfer to New York, but are glad that he has been offered this larger opportunity, and feel sure that he will repeat, on a greater scale, the success which he has attained in New England

MASSACHUSETTS LEGISLATIVE NOTES

THE VETO OF HOUSE BILL NO 1305*

The Governor vetoed House Bill 1305 which was designed to authorize the University of Massachusetts Incorporated to grant the Degree of Bachelor of Science The argument of His Excellency is so cogent that we submit it in full as follows

The Commonwealth of Massachusetts Executive Department Boston Massachusetts March 19 1934

To the Honorable Senate and House of Representatives

I am returning without my approval House Bill 1305 entitled An Act authorizing the University of Massachusetts Incorporated to grant the Degree of Bachelor of Science To recognize this university as eligible to grant the degree of Bachelor of Science holds out to the general public that courses of instruction are given the successful pursuit of which results in a graduate having attained the same scholastic standing as a graduate from the other Massachusetts institutions now granting the degree As a matter of fact there is no course of instruction at the University of Massachusetts Incorporated which furnishes the same instruction received by the recipient of a degree of Bachelor of Science graduating from any of the other institutions of learning now granting the degree This Commonwealth is asked to permit the awarding of a degree of Bachelor of Science in order that the University of Massachusetts Incorporated may set up a course of study in accordance with the recognized educational standards for the degree In other words Massachusetts is asked to grant the degree on faith that the institution will conform to recognized standards and in my opinion the authority to grant degrees should not be conferred in that manner In any event an analysis of the assets educational and otherwise of this institution do (sic) not give sufficient assurance of a maintenance of the high standard which this degree requires to warrant

The record of the veto is as it appears in House Bill 1335

the presumption that such standards will be attained if the degree is permitted.

It may be argued that there is an inconsistency in permitting the Staley College of the Spoken Word to grant a degree of Bachelor of Science of Oratory, but this school has for years conducted a course which, in my opinion, entitles it without change of its curriculum to the reward which the State has imposed upon the earnest efforts of the leaders of that institution, while in the instance of this bill, the University of Massachusetts Incorporated has not yet brought its requirements to the customary standards for the granting of a degree of Bachelor of Science. Furthermore, the degree of Bachelor of Science is granted upon an established standard which has been fundamental to it for a long period of time, while the somewhat newer degree of Bachelor of Science of Oratory has not yet the public recognition of scholarship which the degree provided in this bill holds forth.

There is perhaps a more fundamental difficulty with the bill. The name "Massachusetts" has acquired a standard in matters of education recognized throughout the United States and the world. Its use in the conferring of degrees cannot be permitted except in the absence of doubt as to the ability of the institution to meet such educational standard. The Commonwealth itself sustains an educational institution under the name of the Massachusetts State College which, in the course of time, holds the possibility of developing into a university. This is a precious name which in educational matters should be held as the proud possession of the State itself. It should not be appropriated by any private group, however conscientious the intentions of the group may be, which is without endowment or such considerable public support as to guarantee that the institution will maintain the high scholastic standards which the name and the other institutions of the State represent. The title of Massachusetts University properly belongs to the people of the Commonwealth.

For these reasons I am returning the bill without my approval.

JOSEPH B. ELY

H 118 was submitted by the Board of Registration in Medicine, and the argument in favor of it was published on page 795 of the issue of April 12, 1934. The action of the Legislature is that "no legislation is necessary." This is an indication that the General Court is not interested in raising the standards of medical practice in Massachusetts. This Commonwealth continues to occupy the unenviable distinction of maintaining the lowest standards relating to medical education in this country. We have been admonished to "have faith in Massachusetts" without a time limit.

MISCELLANY

A SAFETY CONFERENCE

Under the auspices of the Massachusetts Safety Council and Coöperating Organizations, invitations have been issued to attend the First New England Safety Conference and the thirteenth Annual Massachusetts Safety Conference to be held in the Hotel Statler, April 30, and May 1, 1934.

Practically all of the unnecessary hazards to life and health will be dealt with.

The Safety Exhibit will be interesting, and Section 6 on occupational diseases is especially important.

In each of the fourteen sections, matters which concern the medical profession will be discussed. A visit to the Hotel Statler and a study of the program will be worthwhile.

RECENT DEATH

BOUVIER—JOSEPH PETER BOUVIER, M.D., of Whitinsville, Massachusetts, died April 2, 1934 in a Woonsocket, R. I., Hospital, of coronary thrombosis. He was born in La Presentation, P. Q., Canada, on July 16, 1880, the son of Michael and Eleanor (Savage) Bouvier.

His premedical education was received at St. Hyacinth Seminary, Montreal, and he acquired his M.D. degree from Laval University, Montreal, June, 1905, and settled in Whitinsville, Massachusetts, in 1905. He joined the Massachusetts Medical Society through the Worcester District Society in 1930, and was a Fellow of the American Medical Association. He is survived by his widow, Mrs. Eva (Ledoux) Bouvier, and four children, Gabrielle, Simmone, John and Phillip.

BOSTON HEALTH LEAGUE

THE ANNUAL MEETING

On the evening of April 12, 1934 the Annual Meeting of the Boston Health League was held in the rooms of the Twentieth Century Club, 3 Joy Street, Boston. After dinner, the League was called to order by the President, Dr. John W. Bartol, and the following reports were submitted:

REPORT OF EXECUTIVE SECRETARY

During the year 1933 the country again has experienced low mortality and morbidity rates, but these rates are necessarily based on estimates of the population, and these estimates, in turn, are based on the assumption that the annual increment to the population since the census enumeration of 1930 was the same as that prevailing during the decennial 1920-1930. The latter assumption, however, is open to challenge. Should our population estimates be considerably higher than the true population, all

our calculated rates as now shown are lower than they really are."* The Children's Bureau reports that indications of undernourishment in school children are being received from some parts of the country. Dr Kleinschmidt of the National Tuberculosis Association has likened our favorable health reports to the free wheeling of an automobile due to the accumulation of years of work, but he warns us that we cannot roll indefinitely upon this reserve and urges that all health programs be strengthened in order to combat effectively accumulative effects of continued privation which may have serious effects, if every possible effort is not made to offset the depression with sound health program.

COST OF MEDICAL CARE

At the Annual Meeting of the Corporation on March 9, 1933 Dr Richard M. Smith presented the final report of the Committee on the Costs of Medical Care. Drs Washburn, Lee, Bigelow, Wilinsky and Bowers discussed briefly the report and it was voted that The Executive Committee of the League be directed to consider how it can best serve the interest of the community at this time with regard to the problems connected with the cost of medical care and that it take such steps during the coming year as may seem in its judgment to be wise.

In June at the request of the Hospital Superintendents Club the Health League called a meeting for discussion of a plan for prepaid hospitalization, which was attended by hospital superintendents, members of the staff and members of the boards of trustees of the hospitals of Greater Boston. Beyond affording opportunity for discussion of the plan, the League has taken no participation in the project up to the present time, but is awaiting further developments before taking action.

CHILD HEALTH RECOVERY

The only other meeting of the Corporation during the year was a luncheon in October when Dr Richard M. Smith and Dr M. Luise Diez reported on the Child Health Recovery Conference called early in October in Washington by Miss Abbott of the Children's Bureau. It was suggested that any plan undertaken in the State should be a permanent one and that examinations should be directed toward the control of all aspects of child health and not merely the detection of children requiring relief because of undernutrition.

DENTAL CARE

During 1933 one of the chief concerns of the Health League has been the lack of adequate facilities for free dental care for adults. The eleven dental clinics in ten hospitals or dispensaries and one settlement house reported that during a year less than ten thousand persons received dental care and this number included children and non residents of Boston. With more than thirty thousand families receiving Overseer's Aid and only 12 1/2 per cent of the total population (781,188 in 1930) under twelve

years of age it is clear that these existing facilities are wholly inadequate. A committee composed of representatives of the Metropolitan District of the Massachusetts Dental Society and the Health League considered the situation carefully and a small demonstration has been started for patients able to pay a part of the regular dental fee. These patients are referred by one agency to members of the Metropolitan District of the Massachusetts Dental Society who have signified their willingness to do this work on a reduced fee schedule. The Committee realizes that this demonstration in no way meets the demand for more free dental work and the problem is still receiving careful consideration.

PNEUMONIA

Because the death rate from lobar pneumonia is rather high in Boston the Metropolitan Life Insurance Company asked the Health League to sponsor an effort to reduce this mortality. The Health League appointed a medical advisory committee of which Dr Frederick T. Lord is chairman and this committee published a brief article in the *New England Journal of Medicine* asking that physicians report cases promptly to the Health Department and that they avail themselves of the Community Health Association nursing service, if the patient cannot afford a private duty nurse. A letter was sent to each member of Norfolk, Suffolk and Middlesex South Medical Societies, who was practicing within the city limits calling attention to this article, a reprint of which was enclosed.

CANCER

The Cancer Committee, during the year has undertaken three definite types of educational lecture work. With the hope of building up informed public opinion a lecture on the biology of cancer was offered to the colleges of Boston, and was given at Simmons College and the Massachusetts College of Pharmacy, and in both places the students were much interested. Eight lectures were given before mothers' clubs in the settlement houses. The third group to be reached was the nurses at the State Convention in October when the committee arranged to have Dr Jackson speak and asked the State Health Department to provide an exhibit on cancer.

One cancer bulletin was published during the year. The leading article was by Clarence Cook Little, Managing Director of the American Society for the Control of Cancer and was entitled *Biology of Cancer*.

SOCIAL HYGIENE

This committee has continued the sponsoring of the Staff Council on Syphilis and Gonorrhea and coöperates with the Massachusetts Society for Social Hygiene in the Boston aspects in a study of social hygiene instruction in the educational system and a proposed institute for nurses.

This committee, at the request of the Committee on the Needs of Ward 9 arranged for a conference with a group of Negro social and church workers,

when Dr Nels A. Nelson, of the Massachusetts State Department of Health, gave an admirable talk on "The Social Significance of Syphilis and Gonorrhea."

SUMMER CAMPS

The committee this year outlined a well rounded daily camp routine emphasizing the necessity for sufficient rest. This routine was adopted by the Division of Tuberculosis of the State Health Department and the Massachusetts Tuberculosis League as a standard for the health camps of Massachusetts. The pamphlet was distributed to about 350 persons who are connected with camps, either in the management or in placing children in camps.

USE OF HEALTH MATERIAL

The office of the Health League continues to be consulted frequently in regard to the various health facilities for Boston and morbidity and mortality statistics, and on three occasions the Executive Secretary presented material at meetings. The Federation of Churches asked the Health League to be responsible for the presentation of health material at the Inter Racial Conference held in April. Graphs showing density of population per inhabited acre and median monthly rental, infant mortality for 1930, 1931, 1932 and the three year average, tuberculosis case rate and tuberculosis death rate for 1930, 1931, 1932, and the three year average by health areas for the city, by census tracts in the South End health area, and by the nine census tracts containing 10 per cent or more Negro population, were shown. Later, the Emergency Planning and Research Board re-drafted the graphs which were in color so they could be reproduced in black and white. The Commissioner and the Division of Tuberculosis in the City Health Department, Boston Tuberculosis Association and the Community Health Association have reproductions of these graphs on file in their offices.

The Executive Secretary was also asked to present the tuberculosis graphs at a joint meeting of the Executive Committee and the Health Education Committee of the Boston Tuberculosis Association, and to speak on health trends in Boston at one of the monthly meetings of the settlement house group.

HOSPITAL GUIDE

In order to supplement the information on file regarding hospital beds and clinical facilities in Boston, in November a "Guide for Social Workers wishing to Secure Free Hospital Care for Clients" was sent to the health and social agencies, who are members of the Boston Health League or the Boston Council of Social Agencies. Many agencies have asked for additional copies and the Guide seems to be helpful in clarifying present policies.

INFANT MORTALITY STUDIES

The three-year graph for infant mortality was also reproduced in the *New England Journal of Medicine* with the infant mortality table by census tracts and health areas for 1932. The three-year average showed very strikingly that the infant mortality rate for Charlestown was in excess of the city rate, while

that for the West End was much less. We await with interest the conclusions of the infant mortality study for 1933 of Charlestown and the West End, which is being made by the Harvard School of Public Health and the Bureau of Research of the Boston Council of Social Agencies, under the auspices of a committee appointed by the Health League.

The Health League, in common with all private agencies, was forced to reduce expenditures during the year, but we are grateful for the loyal support of individual subscribers who designated our agency in the Boston Emergency Relief Campaign of 1933 and to the charitable foundations who have made it possible for us to continue our work without curtailing of activities. This review indicates the many topics in which the League has been interested, and to some extent, we hope, the close relationship between the private and public agencies in joint planning. The Executive Secretary wishes to express her gratitude to the Executive Committee, the many special committees of the Health League, and the public and private agencies without whose help it would have been impossible to carry on such a diversified program with so limited a budget.

MARGARET H. TRACY, *Executive Secretary*,
Boston Health League.

REPORT OF THE TREASURER

During the year 1933, the total expenses of the Health League were \$5,409.49. The cash balance on January 1 was \$250.90. In common with all private agencies, the Boston Health League is experiencing difficulty in financing its program adequately and at the present time is faced with a deficit which will seriously curtail the work during 1934 unless additional funds are forthcoming.

RICHARD G. WADSWORTH, M.D., *Treasurer*,
Boston Health League.

The following officers were elected for the ensuing year:

Honorary President, Francis X. Mahoney, M.D.
President, John W. Bartol, M.D.
Vice President, Rev. Thomas R. Reynolds.
Treasurer, Richard G. Wadsworth, M.D.
Secretary, Charles F. Wilinsky, M.D.
Executive Committee: Gaylord W. Anderson, M.D., Miss Ida M. Cannon, Mrs. Adolphe Ehrlich, Arthur B. Emmons, 2nd, M.D., James A. Keenan, M.D., Horace Morison, Miss Florence M. Patterson, George C. Shattuck, M.D., Wilson G. Smillie, M.D., Richard M. Smith, M.D., Frank E. Wing.

At the close of the business meeting Dr. Bartol introduced Dr. Kendall Emerson, Executive Secretary of the American Public Health Association, who delivered an instructive and stimulating address on the "Essential Public Health Services" which will be published in a subsequent issue of this *Journal*.

The paper was discussed by Dr. Henry D. Chadwick, Massachusetts State Commissioner of Public Health.

THE CUTTER LECTURE ON PREVENTIVE MEDICINE

The Cutter Lecture on Preventive Medicine for this year was given on Friday, March 16, at 5 00 P.M. in Building E of the Harvard Medical School by Dr. Karl Landsteiner, member of the Rockefeller Institute in New York City. His subject was "Immunochemical Specificity."

The speaker was introduced by Dr. Milton J. Rosenau of the Department of Preventive Medicine at the Harvard Medical School. Dr. Landsteiner's pioneer work on the antigen-antibody relationship and his discovery of the human blood groups were briefly mentioned.

After a brief historical survey of the work on the specificity of antigens, especially the proteins, Dr. Landsteiner discussed the methods now being used at the Rockefeller Institute. With the development of the inhibition reaction they have been able to test in detail the immunological specificity of various modified antigens, especially the azo-proteins. The reactions have been found to be the more specific with increasing chain length of the particular modifying group under investigation. Small differences in chemical structure, however, have been shown to produce striking differences in serological reaction. It has even been possible to distinguish *cis-trans* isomerism such as in maleic and fumaric acids. Considerable work is being done at the present time on the specificity of the antigenic reactions of protein split products, albumoses and proteoses.

Dr. Landsteiner next discussed cellular antigens from the chemical point of view. The significance of the bacterial carbohydrate fractions, as in the pneumococcus, was considered. Carbohydrate as an antigen is probably of importance in tissue cells as well as in bacteria. There is hardly any question but that carbohydrate is capable of arousing immune processes without the aid of protein. The immunizing action of lipoids, however, such as the lecithins, is still very doubtful.

In conclusion, the mechanism of antibody formation was very briefly considered and Dr. Landsteiner compared the process with that involved in the formation of a large complex molecule, like a protein molecule.

THE STAMFORD (CONN.) MEDICAL SOCIETY

The Stamford Medical Society held its monthly meeting at the Stamford Hall Sanitarium on Tuesday evening, April 17. Dr. Graeme M. Hammond of New York City read a paper on 'Suggestions in the Treatment of Epilepsy' and Dr. William P. Healy presented a paper on 'Precancerous Lesions of the Vulva and Cervix' illustrated with slides.

Dr. Frank W. Robertson, Medical Director of Stamford Hall, extended greetings to the members of the Society. Dr. Frank C. McMahon, President of The Stamford Medical Society, presided.

At the conclusion of the meeting a collation was served to the members of the Society and guests.

BOSTON MEDICAL HISTORY CLUB

The annual meeting of the Boston Medical History Club was held at the Boston Medical Library on Monday evening, April 16. Dr. Merrill Moore read a short paper on Ulrich von Hutten and Neurosyphilis and Dr. Ralph C. Larrabee gave a very interesting talk on the attempted ascent of Mt. Washington by Dr. Ball, a Fellow of the Massachusetts Medical Society, in October 1855. Dr. Ball was lost for three days in a very severe storm with his trusty umbrella as his sole companion and lived to tell the tale in his little book entitled *The Perilous Adventure of Dr. Ball*.

Dr. Larrabee is an authority on the White Mountains and trail expert of the Appalachian Mountain Club and in 1931 with two companions identified and mapped out the trail of Dr. Ball in his hazardous adventure. This party named the highest point reached by Dr. Ball as Ball's Crag with the hope that it may perpetuate his experience. Dr. Larrabee gave a very graphic account of the perils of the much underestimated Mt. Washington and illustrated his talk with a large number of stereopticon slides.

The annual report of the Secretary-Treasurer showed a balance of \$240.79 after all bills for 1933-34 had been paid, and an active membership of 109. In his report, he called attention to the outstanding programs furnished during the year.

The season began in November 1933 with the third Medical Historical Pageant by students of Tufts College Medical School under the direction of Dr. Benjamin Spector. In December Professor Norman E. Himes of Colgate University read an important paper on the 'Medical History of Contraception' which was published in the *New England Journal of Medicine*, March 15, 1934. In January of this year, Dr. Henry E. Sigerist, Director of the Institute of the History of Medicine at Johns Hopkins University, gave an informal talk on his trip to Italy in 1933 in search of medieval medical manuscripts. His paper has been published in the *Bulletin of the Institute of the History of Medicine*, March 1934. In February, Dr. Francis T. Hunter read a paper on "Mummification" and exhibited x-rays of all the mummies in the Boston Museum of Fine Arts. The March meeting was given over to a symposium on Jewish Medicine based on the manuscripts and books in the "Solomon M. Hyams Collection" and April was reserved for Dr. R. C. Larrabee's very interesting talk on Mt. Washington.

The Secretary commented on the general excellence of the complete program and said that it would be very difficult to duplicate it during the coming year. However, the fourth pageant is assured for November and three very good main papers have been promised for the season of 1934-35 which cares for four of the six regular meetings.

[The page contains extremely faint, illegible text, likely bleed-through from the reverse side. The text is organized into several paragraphs and appears to be a formal document or report.]

Dr Charles F Painter, Chairman of the Nominating Committee, proposed the following names for officers for 1934-35 and all were duly elected

President Henry R. Viets, M.D.

Vice-Presidents Lincoln Davis, M.D., Hyman Morrison, M.D., Harold Bowditch, M.D.

Secretary-Treasurer James F. Ballard.

Council John W. Bartol, M.D., Wm H. Robey, M.D., Fred B. Lund, M.D.

HARVARD MEDICAL SOCIETY

The Harvard Medical Society met in the amphitheatre of the Peter Bent Brigham Hospital on Tuesday evening, April 10. Dr L. Stanley Davidson, Professor of Medicine at the University of Aberdeen, spoke on the Incidence, Etiology, and Treatment of Nutritional Anemia.

The meeting was opened with the presentation of two cases of anemia. The first was a boy, 12 years old, who entered the hospital with the history of an enlarged spleen at the age of five. Since last December he had felt ill and complained of a chronic cough. His mother had spent some time in a tuberculosis sanitarium, but had later been discharged "as not having tuberculosis." The boy tired easily, had a temperature of 102° F., had passed dark colored stools, and had had a gross hematemesis on two occasions. He was, on examination, pale with a rectal temperature of 101° and a pulse of 130. In the midscapular regions there were fine râles on inspiration, and the base of the right lung was flat. A mass in the left upper quadrant extending to the umbilicus suggested an enlarged spleen. Blood examination showed a severe anemia with a hemoglobin of 30 per cent and marked achromia of the red cells. The stools contained occult blood. Pleural effusion was present and the fluid contained 2800 polymorphonuclear cells, 350 lymphocytes, and 350 red blood cells per cubic millimeter, but no tubercle bacilli could be demonstrated. By x-ray there were coarse mottlings of both lung bases. In discussing this case, Dr. Murphy suggested the diagnosis of tuberculosis of the spleen with involvement of the bone marrow. Drs. Minot and Sisson, however, felt that the long duration ruled out this diagnosis and that Banti's disease was more likely.

The second case was that of a woman of 48 years of age showing a marked secondary anemia, due to a neoplasm of the ascending colon which had been surgically removed. Her red cell count on admission had been 3.6 million per cubic millimeter with a hemoglobin of 55 per cent. After treatment the hemoglobin rose to 85 per cent. Dr. Homans stressed the importance of suspecting a neoplasm of the colon when there were local symptoms on the right side of the abdomen with a secondary anemia. When the lesion is in the descending colon there are fewer symptoms.

Dr. Minot introduced Dr. Davidson and stated that King's College, a part of Aberdeen University, founded its medical chair in 1505 and that it repre-

sents the oldest foundation for the teaching of medicine in Great Britain. Dr. Davidson stated that all anemias fall into one of three groups: first, those due to a dietary deficiency, directly or indirectly; secondly, those due to a depression of or interference with blood formation; and thirdly, the hemolytic anemias, either congenital or acquired. Of these groups the first is the most important and the most common. It may in turn be divided into two subgroups: first, the macrocytic, "hyperchromic" type for which liver is a specific; and secondly, the iron deficiency anemias where the cells are microcytic and hypochromic. It was with this second subgroup of the deficiency anemias that Dr. Davidson spent the greater part of his time.

Hypochromic anemias are much more common than the hyperchromic (macrocytic) group. Out of a thousand women of the poorer classes at Aberdeen examined at random, 487 had the hypochromic type while not one had the macrocytic. While the condition does not kill, it leads to a serious lowering of the general vitality with a lowered resistance to infection. Considering the simplicity of the treatment, it is of great importance to recognize the condition.

There are three considerations in the etiology of this defect of the iron metabolism. First, there may be a low iron intake such as occurs from a long continued milk diet in infants or in the low protein, high carbohydrate diet of the adult. Secondly, there may be defective absorption and the rôle played in this respect by gastric achlorhydria needs consideration. Lastly, there may be an increased demand for iron as in blood loss, pregnancy, or infection.

Among the infants of the working classes studied by McKay in London, 50 per cent showed a hypochromic anemia. At birth the hemoglobin is from 120 to 140 per cent and the red cell count is from 6 to 7 million per cubic millimeter. The reason for this is the low oxygen tension in the blood of the fetus which causes the above compensatory mechanism to take place. At this time the bone marrow is also very active. After twelve weeks the hemoglobin has fallen to about 65 per cent. This fall is a physiological result of the relief of the anoxemia after birth and is directly due to a decrease in the bone marrow activity as well as to an increase of cell destruction. Following this period of fall of hemoglobin content, there is a rise to a somewhat higher level, at which level the normal infant stays. In the child of an anemic mother, however, after the fourth or sixth month the hemoglobin again falls to about 60 per cent. The cause for this fall is found in the failure of the infant to accumulate the proper amount of iron in his liver before birth, due to the lack of iron in the mother, so that the normal period of low iron intake during nursing is not compensated for by the stored iron. The proper treatment of this condition is with the pregnant mother, although the anemic child can

also be fed iron with excellent results. No matter how anemic the mother may be, the child is always normal at birth, the low hemoglobin not developing until about the sixth month.

In children from four to fourteen years of age the incidence of anemia is less than one per cent, because in this period of life there are seldom extra demands for iron. In the adolescent period however, chlorosis very frequently used to occur. This happens among young women especially in the employed classes and presents a pronounced hypochromic anemia. High doses of iron cured it and better diet is perhaps responsible for its decrease. At puberty there is an increase in the body metabolism and menstruation is an added drain on the iron stores and it seems probable that this factor in the face of deficient iron intake played a rôle in the production of this disease which is very rare now. The older clinicians stated that in chlorosis there was often an accompanying hyperacidity, gastric ulcers, and occasional hematemesis but upon investigation of these beliefs, Dr Davidson has found that they were not proved by sound experimental or clinical data. The frequency of hypochromic anemia in the middle-aged is astonishing.

In adults, it has been found that the male unless there is an organic cause, will not develop anemia on as low an iron intake as six to eight milligrams per day. Almost all cases of hypochromic anemia occur in women. Among the poor of Aberdeen nearly 50 per cent of the adult women show some degree of anemia. The first factor of importance is the number of pregnancies there being two considerations here first, the fact that the larger the family is the less food the mother will get, and secondly, the added drain of the fetus on the iron supply of the mother. There is a direct relation between the number of pregnancies and the percentage of anemic women in any group. The second factor is the occurrence of achlorhydria (70 per cent of these cases) which may interfere with the utilization of the iron intake. Thirty per cent of the cases showed enlarged spleens. 70 per cent had tongue changes and 51 per cent had nail changes.

The third factor is the diet. When there are special demands on the iron metabolism of the body the low intake of six to eight milligrams per day is not sufficient. These people live on a very high carbohydrate diet, 80 to 90 per cent of it consisting of cereals. Yet many do not develop anemia until additional strain, as pregnancy, blood loss, infection or difficulty in absorption from the gastro-intestinal tract arises.

It is very expensive to correct the diet with regard to the iron intake and the results from such correction are poor. A penny's worth of ferrous chloride or sulphate per day will clear up the condition and act as a preventive measure.

Drs Minot, Murphy and Castle discussed the paper and spoke briefly on chlorosis, the type of iron used and the proper dosage.

CLOVER HILL HOSPITAL

The next medical meeting of the Clover Hill Hospital will be held in the Reception Room of the hospital at 161 Berkeley St., Lawrence on Thursday evening May 3, 1934, at 9 P.M.

The speaker will be Abraham Myerson M.D., Professor of Neurology, Tufts College Medical School.

His subject will be 'The Principal Organic Diseases of the Brain.'

All physicians of Lawrence and vicinity are invited to attend.

N. F. DECESARE, M.D. *Chairman*

HARVARD MEDICAL SOCIETY

The next meeting of the Harvard Medical Society will be held in the Peter Bent Brigham Hospital Amphitheatre (Van Dyke Street entrance), Tuesday evening, May 8, at 8 15 P.M.

PROGRAM

Presentation of Cases.

Factors Controlling the Peripheral Blood Flow in Man. By Dr. Norman E. Freeman.

Studies on the Innervation of the Blood Vessels and Their Application to Neurovascular Surgery. By Dr. James C. White.

Dr. Walter B. Cannon will preside.

JOHN HOMANS, M.D. *Secretary*

THE NEW ENGLAND PEDIATRIC SOCIETY

The spring meeting of the New England Pediatric Society will be held in New Haven, Connecticut, on Saturday, May 19, 1934. Details of the program will be published in this *Journal* at a later date.

GERALD HOFFEL, M.D. *Secretary*

NEW ENGLAND OBSTETRICAL AND GYNECOLOGICAL SOCIETY

The spring meeting of the New England Obstetrical and Gynecological Society is to be held on Wednesday, May 16, 1934, at Portland, Maine.

An extremely interesting program has been arranged.

The registration of members will take place at the Maine General Hospital from 9 00 A.M. until 1 00 P.M., and in the afternoon at the Chamber of Commerce Building, 142 Free Street, from 2 00 P.M. until 5 00 P.M.

FRED J. LYNCH, M.D.

FAULKNER HOSPITAL CLINICAL MEETING

The next meeting will be held at the Faulkner Hospital on Thursday afternoon, May 3, 1934, at 5 00 P.M. In addition to the usual clinical pathological conference on the cases which have come to autopsy during the month, Dr. William W. Howell will give a short discourse on 'The Infant's and Child's Resistance.' All physicians who are interested are cordially invited.

SOCIETY MEETINGS, CONGRESSES AND CONFERENCES

April 26—A Clinic on Pneumonia will be held at 3 30 P M in the amphitheater of the Peter Bent Brigham Hospital

April 27—New England Society of Psychiatry will meet at the Boston State Hospital, Dorchester Center, Mass., at 1 P M

April 30—The American Board of Dermatology and Syphilology Examinations for Certificates Further information may be obtained from the Secretary Dr C Guy Lane 416 Marlboro Street, Boston

May 3—Faulkner Hospital Clinical Meeting See page 933

May 3—Clover Hill Hospital See page 933

May 8—Harvard Medical Society See page 933

May 14, 15, 16, and 17—Thirtieth Annual Meeting of the National Tuberculosis Association For details apply to the National Tuberculosis Association 450 Seventh Avenue, New York City

May 16—New England Obstetrical and Gynecological Society See page 933

May 19—The New England Pediatric Society See page 933

May 26, 27, 28, and 29—The American Association on Mental Deficiency Details may be obtained from the Secretary, Dr Groves B Smith Godfrey Illinois.

June 12—American Heart Association will meet at 9 30 A.M. at the Cleveland Hotel, Cleveland, Ohio

July 24 31—The IVth International Congress of Radiology will be held in Zurich under the presidency of Professor H. R. Schnitz General Secretary Dr H. E. Walther, Gloriastrasse 14, Zurich

September 3 6—American Public Health Association at Pasadena, California Dr J D Dunshee, Chairman, Local Committee on Arrangements

September 4, 5, 6—International Union Against Tuberculosis For information address the National Tuberculosis Association, 450 Seventh Avenue, New York City

DISTRICT MEDICAL SOCIETIES

May 9—Annual Meeting Time and place to be announced later

ERWIN C MILLER, M.D., Secretary

27 Elm Street, Worcester, Mass

BOOK REVIEWS

Researches Published from the Wards and Laboratories of the London Hospital During 1933 London H K Lewis & Company, Ltd Price 7s 6d.

The annual collection of reprints from the London Hospital for 1933 is, as usual, full of splendid material from the laboratories and clinics of this famous institute Chief among the papers collected in this volume are, first, R K Debenham's investigation of 742 cases of haematuria, in which he points out that papilloma and carcinoma of the bladder are the commonest causes in men and inflammatory conditions of the urinary tract the commonest in women The author is strongly of the opinion that all cases of haematuria should be cystoscoped during the attack of bleeding Secondly, Arthur Ellis and Horace Evans report twenty cases of renal dwarfism, a rare condition of great interest, first definitely noted thirty years ago by H M Fletcher Thirdly, William Evans also contributes an excellent paper from the cardiac department of the hospital on congenital stenosis of the aortic arch Lastly, from the department of pathology Dorothy S Russell writes an excellent review of the subject of the tissue culture of gliomas, accompanied by superb illustrations These and other papers speak well for the high type of clinical and laboratory research that is carried on at this hospital

The Interdependence of Medicine with Other Sciences of Nature By William H Welch 48 pp Baltimore The Welch Bibliophilic Society, 1934

In November, 1933, a few friends of Dr William H. Welch of Baltimore gathered together and formed the Welch Bibliophilic Society Their object was to publish texts which were unobtainable in such a fashion as met their requirements of taste The first volume issued by the Society is a reprint of the presidential address given by Dr Welch at a meeting of the American Association for the Advancement of Science in 1907 not previously available in book form A pleasant introduction by Fielding H Garrison points out the value of this work as a contribution to medicine today the best study ever made of the interrelationship of medicine and science This little volume is beautifully printed and bound and is a great credit to this new bibliophilic society Two hundred and twenty-five copies have been issued privately

NUMBER 18

NEW ENGLAND SURGICAL SOCIETY

ACUTE THYROIDITIS WITH REPORT OF TEN CASES*

BY ROBERT C COCHRANE, M.D.,† AND STANLEY J G NOWAK, M.D.†

GLANDS of internal secretion are peculiarly immune to acute infection, their tendency toward pathologic changes lies rather in the direction of dysfunction and tumor formation. Exceptions to this general rule are the thyroid and testis. Acute inflammation of the thyroid gland is not commonly encountered and by reason of its obscurity is subject to errors of management and treatment. It has been our rare privilege to study ten cases of acute thyroiditis at the Boston City Hospital and to observe personally four of these. This experience has enabled us to formulate a conception of diagnosis and treatment which we wish to present in this communication.

Inflammatory lesions of the thyroid may be classified broadly as acute and chronic. The acute form was subclassified by Mygind¹ in 1894 into simple acute and acute suppurative types, each of which he considered a disease sui generis, a view not readily tenable at the present time. Following this simple yet adequate, classification further subdivision was suggested with respect to the presence or absence of adenoma, thus acute thyroiditis represented inflammation of a normal gland while strumitis referred to an acute lesion superimposed on an adenomatous growth. It was further thought that acute thyroiditis remained in the state of acute cellulitis whereas acute strumitis proceeded on to suppuration. These distinctions are not supported by the present-day conception of this disease and it appears that Mygind's original classification of the acute form into simple and suppurative groups can hardly be improved upon.

Although attention was directed toward acute inflammation of the thyroid by Carrion Walter, Conrad and others² in the eighteenth century, only scattered case reports and three collective reviews have made their appearance in literature. As early as 1857, however, Bauchet³ wrote a monograph on the subject with five case reports which remains to the present day a classic for its accuracy and thoroughness of description. Oddly enough this work has not

received its proper recognition. In 1878 before the days of bacteriology Kocher considered acute thyroiditis as of infectious metastatic origin, a view which was subsequently confirmed by Tavel in 1892⁴. Three years later appeared Mygind's classification already referred to. In 1896 Ewald⁵ dispensed with the rigid conception of simple and suppurative thyroiditis as separate disease entities as suggested by Mygind and supported by DeQuervain. The subject remained dormant until the appearance of the collective reviews of Robertson in 1911⁶ of Hagenbuch in 1921⁶ and of Burhans in 1928⁷.

The incidence of thyroiditis is extremely low, estimated at less than one-half per cent of all observed clinical cases of thyroid disease. During the senior author's experience with five hundred thyroidectomies there occurred seven cases, three of which came to operation.

With the exception of several cases in which the infection was due to direct trauma as reported by Link⁸ or extension from a thyroglossal duct as reported by Cleland⁹ the lesion is usually secondary to some other focus as originally stated by Kocher. The frequency with which this condition follows upper respiratory infections points to the lymphatics as an important route of infection. The blood stream also carries organisms to the gland as in cases of puerperal septicemia, typhoid fever, pneumonia, etc. Finally, changes in physiological states such as puberty, menstruation and pregnancy are also well-recognized predisposing factors.

Females are more susceptible to the disease than males in a ratio of two to one. The average age of onset is from twenty to forty, the extreme limits being eighteen months and seventy-seven years.

The history of previous goitre is a rather frequent finding as is shown in thirty-two of the sixty-seven cases of Burhans⁷ and thirty-three of the ninety-six cases of Robertson⁵. On the other hand only five of the forty-three cases of Hagenbuch⁶ showed previous goitre. This factor must be a variable one depending for example, upon the presence of goitre in certain regions. Hyperthyroidism, on the other hand, is rarely complicated by acute thyroiditis. Bothe¹⁰ has, however, reported a case in which the metabolic rate registered plus 42. The disease leads frequently to various degrees of myxedema as re-

Read before the New England Surgical Society at Boston, September 30, 1933.

BOOK REVIEWS

Researches Published from the Wards and Laboratories of the London Hospital During 1933 London H. K. Lewis & Company, Ltd Price 7s 6d

The annual collection of reprints from the London Hospital for 1933 is, as usual, full of splendid material from the laboratories and clinics of this famous institute. Chief among the papers collected in this volume are, first, R. K. Debenham's investigation of 742 cases of haematuria, in which he points out that papilloma and carcinoma of the bladder are the commonest causes in men and inflammatory conditions of the urinary tract the commonest in women. The author is strongly of the opinion that all cases of haematuria should be cystoscoped during the attack of bleeding. Secondly, Arthur Ellis and Horace Evans report twenty cases of renal dwarfism, a rare condition of great interest, first definitely noted thirty years ago by H. M. Fletcher. Thirdly, William Evans also contributes an excellent paper from the cardiac department of the hospital on congenital stenosis of the aortic arch. Lastly, from the department of pathology Dorothy S. Russell writes an excellent review of the subject of the tissue culture of gliomas, accompanied by superb illustrations. These and other papers speak well for the high type of clinical and laboratory research that is carried on at this hospital.

The Interdependence of Medicine with Other Sciences of Nature By William H. Welch 48 pp Baltimore The Welch Bibliophilic Society, 1934

In November, 1933, a few friends of Dr. William H. Welch of Baltimore gathered together and formed the Welch Bibliophilic Society. Their object was to publish texts which were unobtainable in such a fashion as met their requirements of taste. The first volume issued by the Society is a reprint of the presidential address given by Dr. Welch at a meeting of the American Association for the Advancement of Science in 1907 not previously available in book form. A pleasant introduction by Fielding H. Garrison points out the value of this work as a contribution to medicine today, "the best study ever made of the interrelationship of medicine and science." This little volume is beautifully printed and bound and is a great credit to this new bibliophilic society. Two hundred and twenty-five copies have been issued privately.

He flexes it gently forward, chin inclined toward the sternum, he relaxes in a word the subhyoid muscles. The tumefaction obliterated the hollow formed by the junction of the two sternomastoid muscles. This tumor follows the movements, upward and downward, of the larynx. On requesting the patient to drink one observes what goes on in the tumor."

He further describes the course of the disease so accurately that the following extract is also presented. "Thyroiditis lasts in general one or two weeks, the tumor appears on the second or third day, enlarges from the third up to the fifth or sixth day, then if suppuration does not follow, it diminishes from this time and disappears from the fifteenth to the twentieth day. During the early stages the symptoms become aggravated, they remain stationary for a day or two, then disappear more or less quickly, according to the patient and the treatment which was put to use. That is the progress most normal of thyroiditis. If the inflamed thyroid has a tendency to terminate with suppuration the symptoms become aggravated, the fever does not fall around the sixth day, on the contrary, chills manifest themselves, the skin is tense and red, the tumor becomes more painful, softens, and becomes fluctuant. The fluctuation is generally manifested from the tenth to the twentieth day. In case the abscess spreads outward the infection will be more serious and almost always fatal, the pus will fuse with the cellular tissue, follow the trachea, the vessels of the neck, reach as far as the anterior mediastinum or the posterior mediastinum and one understands at once the danger of such complications."

The temperature in simple thyroiditis may be only slightly elevated while suppuration of the gland is associated with a temperature of 102°F sometimes reaching 104°. Occasionally chills and sharp elevation of temperature are observed resembling that seen in malaria. The leukocyte count ranges from 14,000 to 30,000. Positive blood cultures are to be expected in some cases showing, of course, any one of the organisms mentioned.

Of all the conditions for which this disease is mistaken cellulitis of the neck is the most frequent. The latter is extremely rare in the lower half of the neck in the midline. It is found practically always in its greatest intensity in the submaxillary or carotid triangles. It is safe to say that cellulitis confined to the lower half of the front of the neck is secondary to an inflamed thyroid gland, particularly if the gland itself is tender to pressure, if the suprasternal notch is obliterated, and if dysphagia or aphonia are present. Ludwig's angina will show definite ulceration in the pharynx along with submaxillary or submental involvement. Other infectious lesions to be differenti-

ated from thyroiditis are diphtheritic laryngitis and perichondritis of the thyroid cartilage, both of which are rare and which will be recognized by laryngoscopy. Chronic infections of the thyroid of either tuberculous or luetic origin will simulate subacute involvement of the thyroid. The ultimate differentiation will probably rest with the pathological sections. Both adenoma and carcinoma may present a strong resemblance to acute thyroiditis and vice versa. Spontaneous hemorrhage in an adenoma, although rare, may be confused with acute thyroiditis because of its sudden onset, acute pain, swelling and localized tenderness. This condition will not, however, show a constitutional reaction. Simple colloid goitre when characterized by rapid growth will often resemble simple acute thyroiditis because of the swelling and tenderness but again will not be associated with general reaction. Finally, tumors or diverticulae of the esophagus, and tumors of the superior mediastinum need only be mentioned as differential problems.

The prognosis is excellent in simple acute thyroiditis. Resolution will occur under palliative treatment in ten to fourteen days. Robertson⁵ in his series of ninety-six cases reported two deaths in fifty-six cases of simple thyroiditis giving a mortality of 3.5 per cent. In forty suppurative cases he reported nine deaths, giving a mortality of 22.5 per cent. These figures bear out our impression that suppurative disease of the thyroid is a serious condition in contrast to the relatively excellent prognosis of simple acute thyroiditis.

Recurrences in both simple and suppurative types have been reported and were observed in one of our cases.

The complications of the disease are perforation into the larynx or trachea, mediastinitis, pyemia, septic joints, osteomyelitis, myxedema or more rarely thyrotoxicosis.

Treatment of the disease falls into two categories non-operative and operative. Simple acute thyroiditis will yield to supportive treatment consisting of local cold or heat, rest, elevation of the head, and sedatives. The presence or suspicion of a suppurative process calls for early operative incision and drainage. In rare cases of miliary abscesses, partial thyroidectomy has been recommended by Clute and Smith.¹⁴ In the presence of suppurative adenomata, Vianny¹⁵ has advised partial strumectomy ("Strumectomie a chaud primitive") which he has done in three cases. In some cases operative interference will be aimed at relief of the general toxemia resulting from the local lesion, in others it will be directed at relief of pressure symptoms reaching proportions of an emergency. The choice of anesthetic is important, particularly where tracheal obstruction is present. The use of a general anesthetic may cause a dangerous asphyxial spasm of the larynx and upper

ported by Burhans⁷ and Hallberg¹¹. An extreme grade of myxedema has been reported by Wilcox¹² in the case of a girl who developed suppurative thyroiditis from local sepsis after a transcervical removal of a foreign body from the esophagus.

A long list of organisms has been found to cause this lesion. The most common of these are streptococcus hemolyticus, staphylococcus aureus, pneumococcus, typhoid, paratyphoid a, paratyphoid b and colon bacillus. More rarely one encounters malarial parasites and trypanosomes. Thyroiditis has been known to occur after smallpox, measles, rheumatic fever, influenza, diphtheria, and cerebrospinal meningitis.

In 1899 Roger and Garnier¹³ studied the effect of bacteria injected into the common carotid artery which was ligated above the origin of the thyroid arteries. They found the gland little affected after injection of staphylococci and bacilli typhosus. On the other hand the injection of streptococci, diphtheria toxin, tetanus toxin, pilocarpine nitrate and iodides produces definite pathological lesions of acute thyroiditis.

These same workers made the earliest contributions to the pathology of the disease. Their studies were based on postmortem examinations of thirty-three cases following various acute infections such as scarlet fever, measles, diphtheria, typhoid, meningitis, smallpox and streptococcus peritonitis. Microscopically, changes were noted in the acini, in the stroma, and in the blood vessels. The acini were found to be smaller than usual resembling secretions of an infantile thyroid. They were devoid of colloid material which appeared to migrate into the interstitial spaces and lymphatics. The acini showed various degrees of disintegration and their lumina were filled with poorly staining granular cells, the result of earlier desquamation. Throughout they observed a generalized capillary dilation and rare hemorrhages. This description is obviously one of the simple acute type. The suppurative stage is characterized by diffuse polymorphonuclear infiltration, bacterial invasion, and necrosis. For more recent pathological descriptions the publications of Burhans⁷ and of Clute and Smith¹⁴ are recommended.

From this local picture it is apparent that the disease process readily spreads to the surrounding tissues involving the pretracheal muscles, the recurrent laryngeal nerve, the thyroid cartilage, the trachea, the esophagus (with possible perforation of these structures) and spreads under the deep cervical fascia either upward toward the mandible or downward into the anterior mediastinum.

The relationship of acute to chronic thyroiditis is not a clear one. Most writers consider each process a distinct entity. This may well be the general rule but our experience with one case of recurrent acute attacks with evidence of acute necrosis superimposed on a chronic lesion

demonstrates a possible relationship between the acute and chronic processes. Similar findings have been noted by Deaver and Burden¹⁵ and by Vianny¹⁶.

The characteristic symptoms of acute thyroiditis are pain over the gland, dysphagia, hoarseness, dyspnea and chills. Pain may be the initial symptom of the disease. Usually characterized by soreness it may become lancinating and radiate to the ear or the shoulders, undoubtedly a sympathetic phenomenon. It may dominate the picture and direct the attention to the ear.

The presence of a tumor may be the initial symptom in some cases.

Dysphagia is a very prominent complaint. It may vary from slight discomfort to inability to swallow anything but liquids. This symptom is due to the presence of the tumor and is frequently accompanied by a constant desire to swallow because of the feeling of pressure on the esophagus.

Hoarseness is also common and is due probably to an extension of the inflammatory process to the vocal cords or the recurrent nerve. At times the voice is reduced to a whisper. This symptom may be so dominant as to lead to a search for an intralaryngeal growth.

The inflammatory tumor and surrounding reaction inevitably constrict the trachea to produce respiratory obstruction of varying degrees culminating in some cases in asphyxia. This phase of the disease is extremely important in the consideration of the choice of anesthetic.

Hyperthyroidism has been known to occur with the characteristic eye signs, elevated metabolism, nervousness, and so forth, but it is a rare manifestation.

Toxemia, however, may be overwhelming. It is, of course, dependent upon factors chief of which are the nature of the involving organism, the amount of the gland involved, and the resistance of the patient.

The characteristic signs are swelling over one or both lobes of the thyroid with marked local tenderness. Edema is commonly present. Redness, however, is a late sign even in the presence of suppuration. The swelling may preserve the contour of the lobe or gland or it may be diffuse in appearance causing obliteration of the suprasternal notch.

The attitude of the patient is the second most characteristic sign. The patient usually sits up in bed, with head bent forward, with a distressed stare, dyspneic, swallowing frequently, possibly coughing, and unable to raise his voice above a whisper. Bauchet's³ original description brings out most of the important physical features of the disease, some of which have been accredited to various subsequent writers. Let us quote from his historical monograph: "The patient gives to the head a particular position

1	M M F 22 Suppurative	Soreness of lower neck and throat Radiation to both ears	1½ weeks Influenza	Median swelling T—100, P—90, W B C—10,000	I & D Local	Cured 13 days in Hosp	6 months pregnant

trachea, particularly in an individual with a short neck. Where obstruction is a definite possibility we feel that incision and drainage should be carried out under local anesthesia with adequate preoperative medication.

The actual operative procedure consists of the classical collar line incision and exposure of the gland. The abscess which usually points to the surface of the gland or surrounds it is then opened by blunt scissor dissection and drained by rubber dams. The wound is then loosely sutured about the drains. Partial thyroidectomy may be advisable as already stated.

DISCUSSION

It is no exaggeration to say that acute thyroiditis as an entity is unknown to the average internist and surgeon. It frequently masquerades under the name of cellulitis of neck in the suppurative stage or painful goitre in the simple acute stage. We are of the opinion that the disease, although uncommon, is by no means rare and should be considered in all cases of swelling either circumscribed or diffuse in the lower neck associated with inflammatory symptoms and signs.

It follows that the acute surgical aspect in many of these cases has been entirely overlooked either from failure of diagnosis or from inadequate appreciation of the seriousness of the suppurative stage of the disease. Our experience of three deaths in seven suppurative cases shows how grave the disease may be. The common error is that of delayed operation and improper choice of anesthetic. It is, however, highly probable that operative interference in the presence of streptococcus hemolyticus infection before localization of the infection occurs may result in spread of infection into the blood stream. This purely speculative note is mentioned only because surgical experience has repeatedly brought out the danger of too early operative interference in streptococcus infections elsewhere. We reiterate, however, that the prevalent error is that of delayed operation.

The choice of anesthetic has been stressed and the desirability of local anesthesia in most cases is urged. It is absolutely indicated in the presence of obstructive phenomena. The operative technique presents no problems save for the occasional desirability of subtotal resection in the presence of milary abscesses.

The ten cases reported represent both the typical and atypical aspects of the disease. They illustrate the relatively favorable prognosis of the simple acute form in contrast to the serious prognosis of the suppurative form. They bear out the usefulness of this broad classification not only in the matter of prognosis but also in the choice of therapeutic procedure.

Reports of seven cases of acute suppurative thyroiditis and three cases of simple acute thyroiditis follow.

CASE No 1 M. M. (Hosp No 332144) a twenty-two year old single female was admitted to the B. C. H. on Jan 31, 1916 with a complaint of sore throat and soreness in the neck and both ears of one and one-half weeks' duration. These symptoms developed three to four days after the onset of an attack of influenza. Since the onset of these symptoms the patient had noticed general malaise and a slight fever. There was no exophthalmos, tachycardia, or nervousness. The patient had had no previous swelling of the thyroid. The family and past history revealed no significant facts. Physical examination showed a well-developed and well-nourished young female adult. Eyes, ears, nose, and throat showed no abnormality. The neck revealed a marked enlargement in the region of the thyroid, particularly noticeable over the isthmus. This enlargement was moderately tender and felt rather soft. There was no redness of the overlying skin. The heart showed no enlargement or murmurs. The apex rate was 84 and was regular in rhythm. The lungs were clear. The abdomen showed an enlarged uterus of six months pregnancy. The extremities showed no tumor or other abnormalities. The temperature on admission was 100°F, pulse 90-100, respirations 25. The admission white blood count was 10,000, the urine and the Wassermann reaction were negative. On February 2 (two days after admission) an incision and drainage of the thyroid was done under 0.5 per cent procaine by Dr. Lahey. A large abscess was found in the region of the isthmus which yielded thick creamy pus. The postoperative course was uneventful, the temperature reaching normal on the third day. The patient was discharged on the thirteenth day (Feb. 14, 1916).

Diagnosis —Acute Suppurative Thyroiditis, Pregnancy

CASE No 2 K. T. (Hosp No 442678, 443170) a twenty-eight year old married woman was admitted to the B. C. H. on Sept. 8, 1922 with a complaint of sore throat and fever. Three weeks ago the patient noticed a sore throat associated with chills and fever which cleared up in two days. She had a recurrence of these symptoms one week later with similar recovery. Several days before admission the patient had a third attack of the same symptoms. These were characterized by pain in the right side of the throat on swallowing and radiation of this pain to the right ear. There were no symptoms of thyroid toxicity during the present illness or in the past history. The marital history showed three normal pregnancies. Physical examination showed no abnormal findings except in the throat. There was a slight erythema of the pharynx, the tonsils were definitely enlarged and slightly reddened. The right ear drum and canal wall were red and there was bulging of the drum. The temperature was 99.0°F, and pulse 95, respiration 25. Paracentesis was performed on September 9 (one day after admission). One week after admission the patient developed a diffuse swelling and redness over the thyroid region with obliteration of the suprasternal notch. There were no signs of thyroid toxicity. A pre-operative B. M. R. was reported as "normal." On September 18 (two days after development of thyroid swelling) incision and drainage was performed under ether by Dr. Loder. A midline abscess was found. The patient was discharged nine days later (Sept. 28).

Diagnosis —Acute Suppurative Thyroiditis, Acute Pharyngitis, Acute Otitis Media (right)

CASE No 3 P. P. (Hosp No 462947) a forty-five year old Greek married female was admitted to the B. C. H. on September 7, 1923 with a complaint

aureus. Five hours after operation the pulse rose from 125 to 150, the respirations increased to 35. The clinical picture was that of thyroid storm for which the patient was treated. Death occurred, however, twelve hours after operation.

Diagnosis—Acute Suppurative Thyroiditis, Pleuritis, Bronchopneumonia (Right)

CASE No 6 T O (Hosp No 704522) a single white chauffeur was admitted to the B C H on March 30 1933 with the complaint of swelling in the right side of the neck of two weeks duration. This swelling developed during an attack of coryza. One week before admission the patient developed dysphagia which increased up to the point of inability to swallow anything but liquids. On the day of admission swallowing liquids caused severe pain in the thyroid region. Three days before admission the pain radiated from the lower neck to the right ear. The family history was unimportant. The past history revealed diphtheria during childhood influenza in 1913 acute tonsillitis two years ago and tonsillectomy shortly afterward. Physical examination showed no abnormal eye signs in ability to open the mouth beyond one-half the normal limit and swelling over the lower neck region. The swelling was more marked over the right lobe of the thyroid with slight edema of the skin extending over the median portion of the neck filling out the suprasternal notch. There was marked tenderness over the right lobe and slight tenderness over the isthmus. The heart, lungs, abdomen and extremities showed no abnormalities. The admission temperature was 102°F pulse 90 120 respirations 26. The white blood count was 14 500 which rose to 30 250 on the second day. The blood smear showed 98 per cent polymorphonuclears with many young forms 2 per cent lymphocytes. The Kahn reaction was negative. Incision and drainage was done under local anesthesia by Dr C C. Lund. Abscess was found in the right lobe containing thick pus which on culture proved to be streptococcus hemolyticus. The postoperative course was without incident the temperature reaching normal on the fourth day postoperative. On the twenty first day postoperative the patient was discharged. One month after discharge the B M R. was -10 per cent.

Diagnosis—Acute Suppurative Thyroiditis

CASE No 7 E M (Hosp No 585066) a sixty-one year old married white janitor was admitted to the B C H on October 15 1929 with a complaint of dull steady pain in both sides of the neck of two days duration. The onset was very sudden and was associated with nausea vomiting malaise and dysphagia several hours later. The family marital and past history was unimportant. There was no history of thyroid disturbance. The physical examination showed a redness and edema over the right side of the neck and upper chest to the fifth rib anteriorly. The swelling in the neck extended beyond the midline and was tender. Both tonsils were enlarged reddened and covered with a yellowish exudate. The remainder of the examination showed no abnormalities. On admission the temperature was 102°F pulse 105 respirations 25 blood pressure 122/72. The white blood count was 16 800 the red count 4 200 000. On the third day the blood culture showed no growth. The patient's progress showed a sustained temperature and pulse rising to 120 with painful paroxysms of coughing and extreme prostration. Death occurred on the fourth day. Autopsy showed swelling and edema of the anterior portion of the neck and thoracic wall. On the right side of the neck above the clavicle there was a swollen indurated mass which on section showed considerable sero-

purulent fluid. This inflammatory process extended into the anterior mediastinum. Culture of the inflamed area showed streptococcus hemolyticus. The heart showed moderate hypertrophy and coronary sclerosis. The lungs were negative.

Diagnosis—Acute Suppurative Thyroiditis

CASE No 8 M R. (Hosp No 467849) a thirty-six year old married female was admitted to the B C H on Jan. 18, 1924 with a complaint of swelling over the lower neck. The patient had entered with a similar complaint on Dec. 3, 1923 and was discharged four days later. During this admission the patient was seen by Dr Lahey who advised conservative treatment for acute thyroiditis. During the interval there was an increase in the swelling with paroxysms of coughing, dyspnea in the prone position and nervousness. The family history was unimportant. The marital history revealed seven pregnancies, two of which terminated in miscarriages. The past history disclosed an attack of hoarseness without sore throat one year ago. Physical examination showed no abnormalities except for a swelling more marked on the left, extending from the hyoid bone to the suprasternal notch. The swelling was slightly tender. There were no thrills or bruit. The admission temperature was 98.0°F, pulse 87 respirations 21, blood pressure 112/70. The white blood count was 16,200 with a differential count of 61 per cent polymorphonuclears, 24 per cent lymphocytes 10 per cent monocytes, and 5 per cent eosinophiles. The Wassermann reaction was negative. The tenderness and swelling decreased with symptomatic treatment and the patient was discharged on the seventh day (Jan 25 1924).

Diagnosis—Acute Thyroiditis

CASE No 9 J C (Hosp No 480604) a twenty-three year old single male was admitted to the B C H on July 5 1924 with a complaint of tenderness over the left side of the lower neck of one week's duration. The patient had noticed a fullness in the lower neck for the past two years but the swelling began to increase in size one week ago. The past history revealed an accident resulting in concussion one year ago. Physical examination showed a larger pupil on the left with normal reactions. There was a marked symmetrical swelling on both sides of the neck more marked on the left where it reached the size of a hen's egg. This swelling was acutely tender. The heart and lungs were normal. There was definite tremor of both hands. The admission temperature was 101°F, pulse 114 respirations 24. The patient was seen by Dr Ullian who confirmed the diagnosis of acute thyroiditis. The patient's condition improved with symptomatic treatment, the temperature reaching normal on the fourth day. The patient was discharged on the ninth day (July 14, 1924).

Diagnosis—Acute Thyroiditis

CASE No 10 C W (Hosp No 700027) a fifty-five year old white married, housewife was admitted on February 15 1933 with a complaint of pain in the left chest of four days duration. Five weeks before admission the patient developed an acute upper respiratory infection with an unproductive cough. Four days before admission she was seized with severe left pleuritic pain for which she entered the hospital. The family history was unimportant. The marital history disclosed four normal pregnancies. The past history revealed diphtheria at the age of seventeen. Catamenia stopped three years ago. There has been a loss of thirty pounds in the past four years. Physical examination showed signs of fluid with a suggestive underlying atelectasis, because of the displacement of the heart to the right.

of soreness in the neck following the appearance of a swelling in the lower left region of the neck. The swelling had gradually increased in size and along with chills, fever, nervousness, irritability, dyspnea and insomnia. The family history was unimportant, the past history revealed epigastric distress of several years' duration and some gynecological disorder leading to a dilatation and curettage one year ago. The physical examination showed an enlargement of the right lobe of the thyroid the size of an egg. The swelling was hard and irregular extending under the clavicle. The isthmus was palpable the left lobe was slightly enlarged. Redness was present over the mass. No thrill, bruit, or exophthalmos was observed. The patient was continually swallowing because of the pressure of the mass. The remainder of the physical examination showed no abnormality except for a presystolic murmur heard over the precordium, most marked over the apex. There was no cardiac enlargement. The temperature was 98.0°F, pulse 75, respirations 22, white blood count 6,800, blood pressure 132 systolic, 80 diastolic. The urine showed a slight trace of albumin in three out of nine examinations. The Wassermann reaction was negative. The swelling appeared to quiet down with conservative treatment. On the fifteenth day of admission the temperature rose to 104°F with increase of local symptoms. The white blood count was 4,400. A blood smear revealed the following: 68.3 per cent polymorphonuclears, 10 per cent large lymphocytes, 15 per cent small lymphocytes, 0.3 per cent basophiles, 0.3 per cent myelocytes, 2.3 per cent metamyelocytes, 2.8 per cent large mononuclears, 1 per cent eosinophiles. The red blood count was 4,112,000 hemoglobin (Tallqvist) 70 per cent. No malarial parasites were seen. Chills and fever persisted for one week and on the twenty-third day the condition began to improve. At this time the B. M. R. was plus 1 per cent. On the twenty-seventh day the patient was put on a malarial régime of quinine with improvement in the local and general condition. The patient was discharged on the thirtieth day after admission (October 6, 1923).

Diagnosis—Acute Suppurative Thyroiditis

CASE No 4 J. H. (Hosp No 574716) a twenty-eight year old male stenographer was first admitted to the B. C. H. on December 4, 1928 with a complaint of swelling in the lower neck and dysphagia of four days duration. During the past three months he had noticed a loss of forty pounds in weight. There were no other signs of thyroid toxicity. Physical examination showed a well developed adult with moderate dyspnea and unproductive cough. There was a brawny edema over the lower neck, obliterating the suprasternal notch. The throat showed slight redness. On admission the white blood count was 26,600 and the blood culture showed a staphylococcus aureus growth in seventy-two hours. On admission x-ray examination of the chest showed no evidence of pathology. Two weeks after admission the patient developed clinical and x-ray signs of pneumococemia in the left base. Feeding by nasal tube was found necessary because of the difficulty in swallowing. Both neck and chest conditions cleared up, however, and the patient was discharged to the medical wards eight weeks after admission (Oct 29).

Diagnosis—Acute Thyroiditis Bronchopneumonia (Left)

Two weeks after discharge the patient had a recurrence of the neck symptoms characterized chiefly by dysphagia. He attempted domestic treatment for two weeks but found it necessary to be readmitted on December 4. On this admission he showed a diffuse swelling of the neck from the hyoid bone to

the sternum and laterally to the posterior margins of the sternomastoids. There was redness over the lower central portion of this swelling. Deep fluctuation was obtained over the suprasternal notch. Two days after admission the neck was incised and drained. After a few inspirations of gas-oxygen the patient developed complete tracheal obstruction. An immediate tracheotomy was done by Dr. Nowak, but no respiratory exchange could be obtained.

Postmortem examination showed the thyroid gland involved in an infectious process which extended throughout the gland on both sides as irregular small abscesses. The surrounding soft tissue was edematous and small collections of pus and necrosis were found in the upper and lateral regions. The outer limits of the process indicated by dense fibrous tissue at the level of the angle of the jaw above and of the mediastinum below. Sanguinopurulent material was found in the bronchi and larger bronchioles. The smaller bronchioles contained dark red blood. Both lower lobes were atelectatic.

Microscopic analysis of the thyroid gland showed histologically both an acute and chronic inflammatory process present. There is a moderate amount of old fibrous scar tissue found which is infiltrated with plasma cells and monocytes. In these areas the colloid had disappeared to a large extent from follicles.

In addition to this the presence of a definitely acute inflammatory process is shown by the presence of an exudate of polymorphonuclear leucocytes, necrosis of follicles and giant cell formation around bits of free colloid. There are also a few small abscesses to be found. With a Gram stain a few chains of gram positive cocci and rare gram positive lancet shaped diplococci are found in these areas of acute inflammation.

On the periphery of the section are islands of essentially normal thyroid tissue save for slight colloid distention of follicles.

Diagnosis—Acute and chronic thyroiditis.

CASE No 5 A. M. (Hosp No 578185) a thirty-two year old married male was admitted to the B. C. H. on January 28, 1929 with a complaint of difficulty in breathing and swelling in the neck of one week's duration. Twelve days before admission the patient had a mild attack of grippe. Two days later he developed a sore throat and several days later a swelling over the lower neck region. These symptoms increased gradually along with the further development of nervousness and general irritability. The patient also experienced occasional attacks of palpitation. The family, marital and past history disclosed no important facts. The physical examination showed a well-developed and well-nourished adult male sitting up in bed, dyspneic, and slightly cyanotic. There was a slight exophthalmos, definite lid lag and positive von Graefe's sign. The neck showed a moderate diffuse symmetrical swelling over the lower part of the front of the neck from the hyoid bone down to and obliterating the suprasternal notch. There were redness and edema over this swelling. The consistency was firm fluctuation was absent. There was moderate generalized tenderness. The heart was normal. The pulse rate was rapid, ranging from 120-140. Examination of the chest showed dullness, increased breath sounds, increased tactile fremitus and a friction rub over the lower right half posteriorly. There was a slight tremor of both hands. On admission the temperature was 102°F, pulse 120, respirations 27. The white blood count was 20,750. Incision and drainage was done under 1 per cent procaine anesthesia by Dr. R. C. Cochrane. Frank pus was drained from both lobes after division of edematous pretracheal tissues. Culture of the pus showed staphylococcus

tory action of the secretions, another because of the absence of any fixed and abrupt angulations throughout the small intestine while, on the other hand, the colon has a content of a very different nature, also considerable stasis and fixed flexures which may possibly explain the more frequent malignancy in that organ

As regards the symptoms of the disease the individual picture varies somewhat but the basic symptom in all cases has been that of intermittent partial intestinal obstruction. All the patients have had abdominal cramps or distress, gas in the stomach, and much gas in the small intestine manifesting itself by spasms of pain and by loud rumbling noises which have been present in practically all cases.

The lumen of the intestine is apparently temporarily obstructed for a few hours or so and then the patient may get relief for several days or even several weeks before another attack. As the disease advances, the symptoms of obstruction with sudden severe abdominal cramps become more frequent and sooner or later all cases have had nausea and vomiting. The stage at which this nausea and vomiting may occur depends upon two things, the completeness of the obstruction and its nearness to the pylorus, because the more complete or the higher the obstruction, the earlier we will have nausea and vomiting.

The first attack is usually of short duration and is followed by apparently complete recovery. Weeks or months may go by before another acute obstruction occurs but as the disease progresses, these attacks are apt to be more severe and more frequent. The nausea and vomiting become very troublesome and in some cases have been aggravated merely by the sight of food because the attacks always follow soon after the taking of food. The loss of weight has been a very constant symptom. Rankin reports an average loss of twenty-eight pounds in his series. According to Rankin a rather severe secondary anemia has been a prominent symptom but in my experience and in the experience of some other writers the anemia has not been an important part of the picture, at least during the earlier stages.

I believe the reason why anemia has not been prominent in most cases is due to the type of growth which has a tendency to develop dense cicatricial constrictions rather than large ulcerating surfaces. Consequently there has been relatively small loss of blood from this type of lesion. In fact, it is quite unusual to find the story of tarry stools although in many cases it is possible by careful repeated examinations to get positive tests for occult blood.

In regard to general physical examination, there is usually nothing abnormal to be found, particularly in the early stages. Later on there is very apt to be a marked loss of weight and possibly a moderate secondary anemia. In no

case have I been able to feel anything abnormal on palpation of the abdomen, but some reports describe a typical palpable mass which is freely movable although tender and seems to slip away from under the examining fingers. The only other positive abdominal finding is a considerable amount of gas in the small intestine which often gives very marked gurgling and rumbling noises.

The x-ray is helpful from the negative standpoint in that by x-ray we can usually eliminate the question of disease in the stomach, duodenum or gall bladder for in these cases the mistaken diagnosis of peptic ulcer or gall bladder disease is often made because of a similarity in the digestive symptoms. Gotten suggests that if an x-ray is taken, a flat plate of the abdomen should be taken first before any barium is given. If this plate shows dilated loops of small intestine, then it indicates an obstructive lesion somewhere above the ileocecal valve. Under normal conditions the x-ray should not reveal gas in the small bowel.

In many cases when the lesion is high in the jejunum, the barium x-ray of the stomach and upper bowel does give a clue to the diagnosis because there is tremendous dilatation of the duodenum and first portion of the jejunum which may be differentiated from the stomach shadow. As a rule however, fairly extensive and careful x-ray studies are necessary in order to establish a diagnosis of malignancy of the small bowel. (In fact, the records show in these cases that a diagnosis is rarely made before a laparotomy is done.)

As regards the pathology of carcinoma of the small intestine, these lesions are of the adenocarcinoma type and may represent the various grades of malignancy. Grossly as I have stated, the growth is of the cicatricial ring type rather than of the large ulcerative type. This lesion causes gradually increasing obstruction of the lumen of the intestine.

In the majority of cases metastasis occurs early. Rankin states that one of every three of his cases had definite palpable metastases at the time of operation.

The treatment is, of course, purely surgical and the ideal operation is an excision of the tumor followed by an aseptic type of end-to-end anastomosis. Even though there are definite metastases present, it is just as easy and just as safe to do an excision and an end-to-end anastomosis as it is to do a side-to-side short circuit around the growth. Therefore, unless the growth is large and immovable, there is no real reason for leaving it behind. In the earlier operations of this series an excision was done, the ends of the bowel closed, and then a side-to-side anastomosis was made. However with our present technique of doing an aseptic end-to-end anastomosis, this is the operation of choice. Rankin is pessimistic regarding prognosis and states that in his series no patient has lived longer than

X-ray examination showed a resolving pneumonia on the right. The admission temperature was 102°F, pulse 85 respirations 22, blood pressure 110/70. The white blood count was 14,700 with a differential count of 84 per cent polymorphonuclears, 14 per cent lymphocytes, 2 per cent monocytes. The Kahn reaction was negative. On the third day thoracentesis of the right side posteriorly yielded 70 cc of yellowish fluid which was sterile on culture.

The signs of pneumonia persisted with a temperature ranging up to 100 for nine days. The patient's condition seemed to improve during the next five days although the clinical and x-ray signs persisted. Sputum examinations showed no tubercle bacilli. Two blood cultures showed no growth. On the nineteenth day the patient developed swelling and redness over the left side of the lower neck. At this time the temperature was 101.5°, pulse 80, respirations 22. The white count was 11,600. The neck revealed a swelling and redness over the lower neck obliterating the suprasternal notch. There was tenderness over the left lobe of the thyroid reaching up to the level of the hyoid bone. The condition was treated symptomatically. On the following day the temperature rose to 103°F, but the redness and tenderness began to disappear. The patient's general condition continued downhill with persistence of the pneumonic signs in the right lower chest and terminated in death five days after the onset of neck symptoms (Mar 11 1933).

Diagnosis—Acute Thyroiditis, Resolving Pneumonia (Right), ? Pulmonary Tuberculosis, ? Carcinoma of the Lung.

DISCUSSION

DR. GEORGE A. MOORE, Brockton, Mass. I would like to record a case of acute thyroiditis. I saw about two years ago, a man who had spent ten years in the Panama Zone and had been treated several years after that for malaria. He had an enlarged, firm thyroid which seemed malignant. He was seen by an internist who concurred with my diagnosis. He continued to run a very high temperature and we searched for malaria many times and were unable to find it and finally operated upon him.

The thyroid was adherent to the underlying structures and I sacrificed one of the parathyroids. His convalescence was uneventful. The pathological report from Dr. Shields Warren was thyroiditis.

CARCINOMA OF THE SMALL INTESTINE*

BY HORACE K. SOWLES, M.D.†

CARCINOMA of the small intestine is rather uncommon and yet not so rare but that it may be worth while to have a little discussion of it particularly in regard to diagnosis, because it is a condition in which the diagnosis is very seldom made before operation. My interest in the subject was stimulated by the fact that due to a curious turn of chance, I happened to have seen five cases, which is, perhaps, a little unusual in the experience of one operator, the previous small groups of cases which have been reported having been gathered from the records of large clinics.

For instance, Gotten of Memphis was able to find only four cases of carcinoma of the small intestine in the records of twenty thousand patients at the Polyclinic Hospital, and Judd, reporting the cases at the Mayo Clinic up to 1919, found only seventeen. This report of Judd's was supplemented by Rankin and Mayo up to 1929 during which time they found eighteen additional cases, making a total of thirty-five

from the Mayo Clinic. In the records of the Massachusetts General Hospital, I found only six cases in the last ten years.

The literature on the subject is not very abundant and the figures in regard to the incidence of the disease show considerable variation. According to Judd, some clinics reported that as high as 3 per cent of all intestinal carcinomata were found in the small intestine. At the Mayo Clinic, however, where he had checked very carefully both the records and the pathological reports, he found that the incidence of carcinoma of the small intestine was only 0.06 per cent of all the intestinal carcinomata. The total figures from the Mayo Clinic in 1929 were 35 cases of carcinoma of the small intestine compared with 4597 of the large bowel and 4335 of the stomach.

There is no obvious explanation as to why carcinoma should be so relatively rare in the small intestine. There are various theories which may be more or less interesting but not conclusive. Some of these are as follows. Because of the fluid nature of the contents of the small bowel, there is relatively less irritation, another because of the alkalinity or other special inhibi-

†Sowles Horace K.—Chief Surgeon Lawrence Memorial Hospital. For record and address of author see "This Week's Issue" page 971.

pital, where Dr Balch operated on him. Male, aged 35, was admitted in December, 1929 with a story of stomach trouble for five or six months. The probable diagnosis was peptic ulcer. He had a dull, gnawing type of pain and also a definite sharp pain at times which came on several hours after meals, and much gas not always related to the pain. He had suffered a few attacks of vomiting. He thought he had lost five or six pounds in the last few months. Between attacks, he felt perfectly well. Examination was negative except for a good deal of gas gurgling in the small intestine. Exploration showed a band of omentum adherent near the base of the cecum. This was drawn tightly across the lower ileum apparently causing obstruction. The ileum above this region was collapsed but on following upward along the ileum for about eighteen inches, the ileum became normal again. No pathology was felt in the region of the stomach or the rest of the abdominal cavity. He went home from the hospital three weeks after operation and was readmitted again ten days later with a story that since leaving the hospital he had been having constant abdominal cramps with some nausea and vomiting. As soon as he ate solid food it was followed by vomiting. He was re-operated one month after the first operation under the diagnosis of subacute obstruction. There was marked dilatation of the first two feet of the small intestine at which point there was a constricting growth and below it the small bowel was entirely collapsed. There were two small glands in the mesentery which were soft and movable. The growth was excised the ends of the gut were closed with purse-string sutures and a side-to-side anastomosis was done. The patient made a good recovery. The pathological report was adenocarcinoma of the small intestine grade 3. Three years after the excision of the carcinoma the patient reported that he had been losing weight for the last six months his color was bad he tired easily and had some pain in his stomach. On examination he had a moderate secondary anemia with a red count of 3 800 000. On a diet this improved slightly but he still was not well. He said that his digestion was poor and he had a good deal of gas in his stomach and occasionally some vomiting. Nothing definite could be made out on physical examination but a recurrence was suspected. The patient died of recurrence forty months after operation.

In conclusion we can say that carcinoma of the small intestine is relatively rare as compared with carcinoma of the other portions of the gastrointestinal tract. The primary symptoms are those due to an intermittent obstruction and later on loss of weight and moderate secondary anemia. The duration of the symptoms may be from a few weeks to several years and the average is about one year. The erroneous diagnosis of peptic ulcer or gall bladder disease is often made. In suspected cases repeated tests of the stools for occult blood are indicated. As a further means of making a diagnosis careful x-ray examinations should be made. Before giving barium a flat plate of the abdomen is advisable in order to determine whether or not there is pathological gas in the small intestine. Treatment is resection with end-to-end anastomosis. Prognosis according to Rankin, is poor. This small group has happened to show a somewhat better prognosis.

I thought some of you might be interested in the clamp we are using, two Kocher clamps joined together by an anchoring device on the shank, and the bowel can be cut off with a cautery close to the clamp, making aseptic ends. Then the ends can be sewed, and the clamps withdrawn. This is a clamp which has been devised by Dr Young.

DISCUSSION

DR. PHILEMON E. TRUESDALE, Fall River, Mass. Dr Sowles has described all the important features of this condition. He has made it clear that there is difficulty in making the diagnosis. My experience is limited to one case. The patient was a woman, forty-five years of age, who entered the hospital in August, 1914 with a diagnosis of acute intestinal obstruction. It had been stated in the history that she had other attacks of a similar nature but not so severe.

On physical examination the upper abdomen was distended but the lower portion of the abdomen was not distended. Naturally, we thought of pyloric obstruction but the patient vomited bile. Then we considered pancreatitis but when the stomach was deflated with a stomach tube, no mass could be felt. Yet this patient was very sick. We operated upon her, expecting to find pyloric obstruction. There was no obstruction at the pylorus, no sign of ulcer, nothing abnormal about the gall bladder, and the pancreas was normal. In exploring the abdomen further I happened to come upon a small mass about as large as an English walnut and brought it to the surface. It was an annular carcinoma of the jejunum. It was resected and an end-to-end anastomosis was made. The patient recovered. I have examined her record and found that she died one year later from metastasis to the liver.

In these cases especially when the intestine is obstructed I doubt if the diagnosis can be correctly made before operation. In fact, the surgeon is fortunate if he finds the lesion during operation. The element of chance as in my case, plays an important part in the discovery of the tumor.

The illustration* represents the specimen of the jejunum resected in the case reported above. The carcinoma appears in the form of an annular growth constricting the intestinal lumen at the center of the specimen.

DR. ALFRED M. ROWLEY, Hartford, Conn. I have enjoyed Dr Sowles' presentation of this subject. I think he has had an unusual experience meeting five such cases. Certainly carcinoma and carcinoid intrinsic tumors of the small bowel are comparatively rare. Extrinsic tumors, metastatic tumors are not so rare.

Why the rarity? Dr Sowles has spoken of the alkalinity. This does not entirely satisfy as some of the appendages to the small bowel such as the biliary ducts are subject to intrinsic intraductal carcinomata. We have met three such cases in the last three years. Also we had one case of carcinoma of a patient with persistent mesenteric duct. Embryologically the small bowel is a primordial structure. This may possibly explain its greater resistance to disease.

I have reviewed the number of cases that we have had at the Hartford Hospital in the last eight years. This represents exclusive of eye, ear, nose and dental work about 40 000 operations and approximately 15 000 laparotomies. We have had two carcinomata,

*Not submitted for reproduction.

three years. The average length of life following operation has been less than a year.

In connection with the above, I wish to report the following case histories:

I. Female, aged 46, was admitted to the Lawrence Memorial Hospital in Medford May 17, 1926 with the following story. During the last three to four years she had lost considerable weight, had been troubled with gastric distress, and had vomited at times. She had never vomited any blood and had never noted any dark colored stools. She complained of no other symptoms. She was given x-ray studies, including a barium meal and Graham test for gall bladder disease. These showed a persistent constriction over the greater curvature of the stomach which was diagnosed as a probable carcinoma of the stomach. The gall bladder failed to visualize. Under the diagnosis of probable carcinoma of the stomach, a laparotomy was done. The stomach and duodenum were normal. The duodenum was somewhat dilated but the rest of the intestinal tract was apparently normal. The gall bladder was large and thickened and contained stones. The gall bladder was removed. The pathological report was cholecystitis and cholelithiasis. The patient made a comfortable convalescence and was discharged fourteen days after operation. The day before she went home she complained of nausea, vomited once, and said she had gas pains in the epigastrium. After discharge from the hospital the troublesome gas pains and vomiting continued. The vomiting became more severe until it occurred after nearly every meal. She finally was readmitted to the hospital six weeks after discharge with a diagnosis of subacute obstruction. Visible peristalsis could be seen in her upper abdomen after anything was taken into the stomach. An exploration was made under a diagnosis of intestinal obstruction. The jejunum and upper ileum were tremendously dilated. There was a small annular growth in the upper ileum causing apparently nearly complete obstruction. This tumor was excised, the ends of the bowel closed, and a lateral anastomosis was done. The pathological report was adenocarcinoma of moderate malignancy. The patient made an uneventful recovery. She is perfectly well at the present time, seven years after operation and weighs forty pounds more than she did when she left the hospital.

II. Female, aged 36, admitted to the Faulkner Hospital March 11, 1930. Her chief complaint was pain in the epigastrium with persistent nausea and vomiting. The duration of the symptoms was seven months for which time she had been troubled with marked indigestion, severe intermittent gas pains, and very marked loss of weight. She vomited everything that she ate. Laparotomy was performed. The upper ileum was tremendously distended down to a point where there was a constricting growth at about the mid portion of the ileum. Below this growth, the ileum was collapsed. This tumor was excised, the ends of the bowel were closed with purse-string sutures, and a side-to-side anastomosis made. The pathological report was adenocarcinoma, grade 3. The patient made a fairly good recovery, complicated by an acute phlebitis of the leg, and was finally discharged thirty days after operation. She did very well for two years and then began to have a recurrence of symptoms. She had nausea and vomiting after every meal so that she could not bear to take any food because of the discomfort which immediately followed. During six months she had lost weight steadily, going from 130 to 85 pounds. She was readmitted two and a half years after the first operation and after taking twenty four hours in

which to overcome her extreme dehydration by means of intravenous glucose solution and subcutaneous salt solution, an exploration was made. There was a large, hard, nodular mass involving the retroperitoneal region about the head of the pancreas and behind the duodenum. Pressure from this mass caused practically complete obstruction of the third portion of the duodenum. It was impossible to remove the mass and a posterior gastroenterostomy was performed to relieve the obstruction. She made a fairly good recovery although continuing to have occasional attacks of nausea while in the hospital, but she gained a little weight and was discharged three weeks after operation. She died four months later, thirty four months after the first operation.

III. Male, aged 43, was admitted to the Massachusetts General Hospital in June, 1931 with a story of vomiting for eleven months and more recently vomiting of everything which he had taken into his stomach. He had lost twenty four pounds in weight. Physical examination was negative and the first impression was probable gall bladder disease or ulcer of the duodenum. He was studied for some little time on the medical side with repeated x-ray examinations. The first barium meal showed a small residue in the stomach at the end of twelve hours and showed some definite spasm of the stomach and duodenum. The x-ray interpretation was definite secondary signs of ulcer, but no filling defect and no definite ulcer were seen. The gall bladder x-rays were negative. A week later another barium meal was given. This time they could distinguish a very much dilated jejunum which partially obscured the shadow of the stomach and a diagnosis was made of an obstruction in the upper jejunum. He was transferred to the surgical side and was operated on July 2, 1931. The upper jejunum was tremendously dilated. There was a constricting tumor of the jejunum about twelve inches from the ligament of Treitz, no palpable metastases in the mesentery, and no sign of metastases in the liver. This tumor was excised and an end-to-end anastomosis was done by means of the Young clamp. The patient made a very uneventful recovery and started to gain weight while still in the hospital. He was discharged two weeks after operation. The pathological report was adenocarcinoma of high grade malignancy. At the present time, twenty six months after operation, the patient reports that he is perfectly well.

IV. Male aged 35, admitted to the Lawrence Memorial Hospital May 18, 1933 with a diagnosis of acute appendicitis. Ten days before admission he had been seized with abdominal pain in the right lower quadrant accompanied by nausea and vomiting. This subsided after a day but the soreness remained. There was another attack of pain the day before admission but less severe. He was seen by his local doctor and sent into the hospital where he was admitted with a temperature of 99.2, pulse 90, respiration 22, white count 12,400. There was definite tenderness and spasm over the right lower quadrant. He was operated on under the diagnosis of subacute appendicitis. The appendix was swollen and edematous but there was a mass two inches in diameter involving the middle ileum with numerous metastatic mesenteric glands and numerous nodules in the liver. A specimen was removed for diagnosis but resection was not done because the disease was evidently inoperable and there did not seem to be any imminent danger of obstruction to the ileum. The pathologist reported adenocarcinoma, grade 3. The patient died three months later.

V. The last case is not my own but one that I saw with Dr. F. G. Balch, Sr. at the Faulkner Hos-

EXCISION OF THE THORACIC OESOPHAGUS
FOR CARCINOMA*

With Construction of an Extra-Thoracic Gullet

BY GEORGE GREY TURNER, M S I

THE patient was a man 58 years of age, one of the best type of North country miners, who was always bright and cheerful and anxious to coöperate in every way with those in charge of his case. He gave a history of difficulty in swallowing of only eight weeks' duration. His complaint was that solid food appeared to stick at the lower end of the breast bone, and that he could only manage to swallow foods of the consistency of porridge and well-masticated bread. After treatment from his

attempt to carry out the operation for the removal of the thoracic oesophagus by the pull-through method which I described in my Henry Jacob Bigelow lecture ‡

On Friday April 28th under general anaesthesia, the abdomen was opened by a high median incision. The left lobe of the liver was separated from the diaphragm and the abdominal oesophagus exposed. About 10 ccm of a ½ per cent solution of novocain was injected through the hiatus into the oesophageal tunnel in the hope of displacing the pleura out of harm's way. The peritoneum in the neighborhood of the hiatus having been incised the finger was inserted into the posterior mediastinum and enucleation of the oesophagus commenced. I found that I could carry my finger all round the growth but I could not get above it. Having accomplished as much as possible by this route the venue was changed to the neck. The cervical oesophagus was exposed through a transverse incision dividing the sternomastoid. By working downwards with the finger in the cellular tissue I was able to reach the upper limit of the growth and to separate the oesophagus from its connexions down to that point. The gullet was then ligatured and divided low in the neck and the upper end was brought to the surface through an independent button-hole incision to the margins of which it was carefully fixed. The division of the oesophagus was made with the cautery and its cut end and the upper part of the tunnel were well smeared with Bipp. The ligatured end was allowed to retract into the mediastinum and the neck wound was carefully closed. A return was now made to the abdomen but on drawing on the oesophagus it was found to be still firmly attached. With the fingers working in the posterior mediastinum it was eventually completely loosened the left vagus nerve being divided with the scissors low down while the right nerve was not seen though it may have been torn through. At this stage it was clear that a hole had been torn into the right pleura and that air was rushing very freely into the chest cavity. This was arrested by stitching the left lobe of the liver over the oesophageal hiatus like a lid. The oesophagus was then ligatured at the cardia and cut away the stump being carefully buried in the stomach by a series of purse-string sutures. The patient made a very good recovery from this operation and without any unusual disturbance. After four weeks he was ready to go home to complete convalescence.

On June 20th he returned to the hospital and on the 25th I carried out the first stage of the operation for the construction of an antethoracic oesophagus. This was carried out by making a tube from the skin of the front of the chest for the middle portion after the plan devised by Rovsing of Copenhagen. The lower end was completed by the Tarvel method using an isolated portion of jejunum for the purpose. The orifice of the upper end of the oesophagus at the root of the neck was connected with the skin tube by a further skin plastic operation. During convalescence the patient developed a fistula at the junction of the skin tube with the intestine and

FIG 1 Radiogram showing constricting neoplasm in middle of oesophagus.

own doctor he improved a little, but the disability was really progressive for during the eight weeks he had lost no less than 3 st in weight. There were no external physical signs whatever, but the x-ray appearances were characteristic of a constricting neoplasm of the middle of the oesophagus (Fig 1).

On April 5th of this year (1933) gastrostomy was carried out and at the same time it was determined that there were no secondary deposits in the liver or in the glands along the lesser curvature of the stomach. The man commenced to pick up immediately. After careful consideration I determined to

one sarcoma and one carcinoid tumor of the small bowel

Pathologically, it may be difficult to distinguish diffuse carcinomata from sarcomata. One of our cases was difficult to classify. However, it was reported on by our pathologist and confirmed by Dr Ewing as a large cell carcinoma and not a sarcoma.

DR WALTER C SEELYE, Worcester, Mass. The case at hand is interesting in that the terminal metastasis was a carcinoma of the small intestine. This was a young woman only twenty-two years old who came in on the first occasion with a complete obstruction due to carcinoma of the transverse colon which was resected and an end-to-end anastomosis made with perfect recovery. Two years subsequently she came in with a large tumor filling the entire pelvis, extending above the umbilicus. Operation revealed a large ovarian tumor which was a metastasis from the transverse colon tumor, showing colloid carcinoma. This was removed, the other ovary and tube were normal and no other abnormalities were found in the abdomen.

Within a year after that time she came in again presenting identically the same picture as the last, with the pelvis and lower abdomen full of a tumor the same size as the first one. This was removed and found to be a tumor of the other ovary similar to the first one, and with identical pathology.

A fourth metastasis occurred about a year later causing complete obstruction from carcinoma in the ileum. That showed an annular carcinoma of small size and this in turn was resected with an end-to-end anastomosis, relieving her of the obstruction, but in this last operation the abdomen showed besides this annular carcinoma of the ileum, a marked and diffuse carcinomatosis of the peritoneal cavity.

DR ERNEST M DALAND, Boston, Mass. I looked up the records of the Pondville State Hospital. There were 3800 cancer cases with 450 autopsies. There was no case of cancer of the small intestine.

DR GEORGE A MOORE, Brockton, Mass. I should like to ask Dr Sowles if he found any records in the literature of primary carcinoma of the small intestine causing intussusception. In 1929 I saw a man of seventy-five who had primary adenocarcinoma of the ileum causing intermittent obstruction for about six months, and finally an intussusception. At operation excision and end-to-end anastomosis were done with an uneventful recovery.

Kasemeyer in 1912 stated that in a series of 199 cases of intussusception resulting from tumors, 85 were malignant in origin.

DR TRUESDALE. What part of the ileum?

DR. MOORE. About three feet from the ileocecal valve.

DR FRED B LUND, Boston, Mass. Unless I am mistaken, a not uncommon location of intestinal carcinoma has been the fourth portion of the duodenum. I had one such case where the resection was difficult on account of the depth. I have seen many intussusceptions caused by tumors of the intestines, one of them showing two such intussusceptions. A man came in to the Carney Hospital two or three years ago, looking as if he had suffered from malignant disease for a long time. He had acute intestinal obstruction and we found two intussusceptions, both of the jejunum, and resected them. The tumors were quite black and the pathologic report was melanotic sarcoma of the small intestine, producing the intussusceptions. Melanotic tumors are usually metastatic from disease of the eye. His eyes were normal. He went home and lived about a month, and the primary source was never found.

DR HORACE K. SOWLES, Boston, Mass. I was hoping Dr Miller might say a word on this because I happen to know he has been over the records of the Massachusetts General Hospital very carefully and checked up the pathological reports on all cases, and I believe he told me some little time ago that he was able to find in all about fourteen in his entire review.

It is rather interesting that two of these cases were operated upon without finding the lesion, and I think Dr Truesdale will probably confirm my statement that it would be very easy to overlook one of these little tumors of the small bowel if you didn't have a pretty definite suspicion it was there. You can run your hand very easily through the abdomen without touching it, and that is what happened in two of these cases, because in one case there was no suspicion of its being there and in the other case apparently adequate cause was found for the obstructive symptoms.

About the question of intussusception, I didn't find any particular mention of that in the literature, but it seems perfectly logical mechanically that a tumor of this sort, a small, constricting carcinoma or fibrosarcoma could easily cause intussusception. A tumor of the small bowel I should suspect might be the most common cause of it in adults. As to the fibrosarcomas and the sarcoma type of tumors according to the literature they are also rare probably with about the same degree of frequency as the carcinomata.

In regard to carcinomata of the duodenum, I did not consider those in my paper. Carcinoma of the duodenum, especially at the papilla, is not uncommon. Whether it originates in the biliary ducts or intestinal mucosa is sometimes a question.

MORTALITY RATES

Telegraphic returns from 86 cities, with a total population of thirty-seven millions for the week ending April 14 indicate a mortality rate of 12.4 as against a rate of 11.1 for the corresponding week of last year. The highest rate (20.4) appears for Richmond, Va., and the lowest (4.3) for Yonkers, N. Y. The highest infant mortality rate (20.9) appears for El Paso, Texas, and the lowest for Canton, Ohio, Fort Worth, Texas, Oakland, Calif. and Schenectady, N. Y., which report no infant mortality.

The annual rate for 86 cities is 12.6 for the fifteen weeks of 1934 as against a rate of 12.1 for the corresponding period of the previous year.

few years They have been almost unanimous in showing better results with the low cervical type than with the classical section

It may be interesting to give briefly the incidence as it occurs in various localities Humpstone¹, shows a frequency of 1 in 22 in Brooklyn Adams², 1 in 89 in Portland, Oregon Skeel and Jordan³, 1 in 44 in Cleveland Johnston and Smith⁴, 1 in 36 in Texas Greenhill⁵, 1 in 48.5 from the Chicago Lying-In Hospital Preissecker⁶, in Vienna a percentage of 3.08 Where yearly reports have been followed it is found (Hawks⁷, Ilkewitz and Seltzky⁸ and Courtiss and Fisher¹³) that the incidence has risen markedly in the last decade as compared with the previous one The incidence, with the exception of those hospitals having an organized home district, may be higher than that of the community at large

The mortality from the operation as published from various centres is as follows Preissecker⁶ (Vienna) gives 5.7 per cent gross for classical sections, laparotrachelotomies and extraperitoneal operations combined Seeley⁹ shows a mortality in the city of Detroit up to 1925 of 13 per cent, and since then to 1930 of 4.43 per cent Skeel and Jordan³ found in Cleveland a 7.6 per cent mortality in 827 classicals and 2.8 per cent in 108 cervical sections Humpstone¹ has 4.3 per cent Hawks⁷ (New York) reported 3.6 per cent for 582 cases of both types Thompson¹⁰ reports from Los Angeles 1322 cases of both types with a mortality of 4.2 per cent The range was from none to 9 per cent according to the hospital Phaneuf¹¹, reports 4.18 per cent personal cervical sections with a gross mortality of 5 per cent and 193 transverse low cervical operations with 3 per cent gross mortality At the Chicago Lying-In Hospital Greenhill⁵ analyzed 874 cervical sections (1.26 per cent mortality) and 147 classical (4.76 per cent mortality) E. v. Ammon¹² collected figures from a thorough review of the American and German literature There were 5,865 laparotrachelotomies (4.1 per cent gross and 2.1 per cent corrected mortality), and 2,685 classical operations (5.9 per cent gross and 2.6 per cent corrected mortality) Courtiss and Fisher¹³ (Boston) report from 1911 to 1919, 214 classical sections (10.2 per cent mortality), from 1920 to 1931, 376 low cervical sections with 1.33 per cent mortality, and 409 classical sections with 6.4 per cent mortality

During the years 1924 to 1932 inclusive there were performed at the Cambridge Hospital, Cambridge, Massachusetts and St Elizabeth's Hospital, Brighton, Massachusetts, four hundred and thirty-six cesarean sections These were performed by forty-four different operators There were, during this period, thirteen thousand one hundred and fifty-four deliveries The incidence of section is then, approximately one in thirty The indications were as follows

Repeat	124
Disproportion, vertex presentation	91
Disproportion, breech presentation	9
Toxemia (nephritis 4 cases)	37
Placenta previa	27
Eclampsia	20
Previous repair	13
Heart disease	6
Separation of placenta	14
Fibroids	5
Inertia uterus	4
Elderly primipara	4
Elderly primipara breech	2
Miscellaneous	14
	<hr/>
	370
Not specified	66

The types of anesthetics, and the frequency of their employment are as follows

Ether	381
Spinal	31
Novocain infiltration	20
Avertin	2
Morphia and gas oxygen	1
No anesthetic (coma)	1
	<hr/>
Total	436

There were no deaths directly attributable to the anesthetic

In the four hundred and thirty-six cases there were twenty deaths, a mortality of 4.6 per cent Eliminating two moribund eclamptics and a case of Addison's disease practically moribund the corrected mortality is 3.9 per cent. Contrasting the two types of operation, classical and low cervical, we find two hundred and ninety-six classicals with twelve deaths, or 4 per cent Correcting for the above-mentioned three cases all of which occurred in the classical series we have nine deaths or 2.1 per cent mortality for the classical section There were one hundred and thirty-three low cervical cases with seven deaths, or 5.3 per cent mortality No corrections were necessary There were three Hirst cases with one death and four sections plus hysterectomy with no deaths

There were four hundred and forty-three babies twins occurring in seven cases There was a gross fetal mortality of forty-two cases, 9.5 per cent The causes are as follows (1) Prematurity, seventeen cases (2) Stillborn sixteen cases The cause was unknown in three of these Maternal hemorrhage accounted for four Eclampsia caused four Toxemia resulted in five (two babies had edema and one probable septicemia) (3) Cerebral hemorrhage caused two deaths (4) Monstrosities occurred twice (5) Congenital heart was diagnosed twice (6) Pylorospasm and skin infection accounted for one case (7) There was one case of myelogenous leukemia. Autopsy was performed in three cases (7 per cent)

The following factors were analyzed (1) distention, (2) morbidity, (3) morbidity after a trial of labor, (4) the maternal mortality and morbidity, and the fetal mortality in placenta

this required two operations for its repair. On the 206th day after the excision of the oesophagus the patient ate a meal consisting of three slices of bread and butter with a poached egg, half a pint of tea, and two pears (Fig 2). This he enjoyed thoroughly.

FIG 2 Patient enjoying a high tea some seven months after the excision of his oesophagus

ly and in his own words "he was able to swallow it just as well as ordinary." The specimen (Fig 3) is a beautiful example of a comparatively localised squamous-celled carcinoma, and though it has invaded the muscular wall, there is no evidence of extension beyond

Of course it is obviously far too soon to judge of the result from the point of view of the treatment of malignant disease, but this case at least

shows that the operation which I have for so long had in mind can be carried to a successful issue and it does demonstrate the great value of the

CESAREAN SECTION A REVIEW OF FOUR HUNDRED AND THIRTY-SIX CASES

BY CORNELIUS T O'CONNOR, M.D.*

IN a review of cesarean section where a comparison is being made of the different types of operations it would seem that several factors must be considered if the analysis is to have value (1) The series, if the classical and low cervical types of operation are to be compared, should be contemporaneous. A comparison of the results of classical section done, for example, from 1905 to 1920 with the results of laparotrachelotomies done from 1925 to 1932 is not fair to the older operation. Refinements in operative technique have been made. Almost everywhere the incidence has increased so that elective sections, or sections early in labor are done more frequently (2) If a clinic reserves the classical section for those cases where speed is essential, e.g., eclampsia, heart disease, placenta previa, etc., its classical group comprises poorer risks as compared with the low cervical, unless

the latter shows a definitely greater incidence of ruptured membranes, longer labors or other factors that would increase the chances of infection (3) A comparison of cases having a test of labor is necessary (4) One should not consider the mortality and morbidity reports of highly skillful operators or well organized maternity clinics, and compare these results with those of city surveys that embrace every degree of prenatal care, organization and operative ability, and then attempt to draw conclusions favorable to one or the other type of operation (5) The gross mortality should be stated. It seems only sensible to subtract fatalities when the patient is moribund, or practically so, before the operation. "Corrections" made for deaths after operation should be done carefully if at all. When made, the details should be stated so that the reader may have access to all the facts.

Many series have been reported in the last

*O'Connor Cornelius T—Visiting Gynecologist at St Elizabeth's Hospital Brighton Mass. For record and address of author see 'This Week's Issue' page 971

sections did not have so good a test of labor as the seven classical cases

The classical group with marked sepsis consists of eleven cases with data in seven. All seven had ruptured membranes, were in labor a long while, and were examined vaginally. Of the three deaths, occurring in these classical sections that had a test of labor, all came in the markedly morbid group. Four low cervical cases had marked sepsis. One had repeated attempts at delivery at home. One had ruptured membranes for five days. One had a long labor and unruptured membranes. In both classical and

4 (b) *Eclampsia* 20 cases

There were nineteen classical sections. There was one Hirst operation. The maternal mortality was five, or 20 per cent. Inasmuch as two were moribund the corrected mortality is 16 per cent. Marked distention was very common in these cases and the convalescence as a rule quite stormy. Five babies died, or 25 per cent.

4 (c) *Separation of Placenta* 14 cases

A toxemia was definitely present in eight instances. In three there was no toxemia. The presence or absence was not noted in two, and

TABLE 3
MORBIDITY OF CASES IN LABOR

Classical 44				Low Cervical 27			
Afebrile	Morbid			Afebrile	Morbid		
	Slight	Moderate	Marked		Slight	Moderate	Marked
17 (39%)	6 (11.5%)	10 (23%)	11 (25%)	15 (55.5%)	4 (15%)	4 (15%)	4 (15%)

low cervical types where marked sepsis followed, labor was long in all cases, membranes were ruptured a long while except in one instance, and vaginal examinations had been made often.

If one subtracts the results of those cases in labor from the whole group, the morbidity of those cases that did not have a test of labor will be shown. There is found a difference of four per cent in favor of the cervical section. The greater difference in the group as a whole is then, accounted for by the group that had a test of labor.

another case, labeled separation of the placenta, had a bicornate ruptured uterus, and really comes under the heading, Rupture of the Uterus. There were no maternal deaths. Ten infants died, 70 per cent. Eight were stillborn and two died shortly after birth from prematurity. There were eight classical sections. Seven were afebrile. Four of these were noted as toxic. One had moderate morbidity with phlebitis. There were two cervical sections. Both were toxic. One was afebrile, and one showed moderate morbidity. Three had hysterectomies. Two were afebrile and one had a slight fever. One case

TABLE 4
(A) PLACENTA PREVIA—27 CASES

Classical 19				Low Cervical 8			
Afebrile	Morbid			Afebrile	Morbid		
	Slight	Moderate	Marked		Slight	Moderate	Marked
9 (47.7%)	4 (21%)	3 (15.1%)	3 (15.1%)	6 (75%)	0	2 (25%)	0

There was one death (3.7 per cent). Nineteen were classical sections with one death (5 per cent). Eight were low cervical cases with no deaths. Forty-seven and seven-tenths per cent of the classical were afebrile as compared with sixty-one per cent in the whole group of classical sections, and thirty-nine per cent in those which had a test of labor. In each of the three classes of morbidity, slight, moderate and severe, there was one case packed. In the two low cervical cases with moderate morbidity neither was packed. One, however had a vaginal examination at home, and the other entered the hospital with ruptured membranes.

The fetal deaths were five, approximately 18 per cent. The low cervical group showed less morbidity than the classical.

was toxic, one non-toxic, and one a case of bicornate uterus.

4 (d) *Toxemia* cases 37—deaths 4, or 10.8 per cent

There were 21 classical sections with one death—5 per cent.

There were 14 low cervical sections with three deaths—21.4 per cent.

There was one Hirst section with no death. There was one hysterectomy with no death. Table 5 shows the morbidity.

There is practically no difference to be noted between the two types of operation. Nor is there to be noted any significant difference between this group and the group as a whole (see table 2). In the classical group of twenty-one

previa, toxemia, separated placenta and eclampsia

1 Distention

In two hundred and eight cases the surgeon's notes and nurse's bedside charts were carefully followed in order to determine the relative incidence, and degree of distention in both types of operations. These were taken from only one hospital, as the nurse's notes were considered essential in getting a proper evaluation of this factor, and these notes were present in only one of the two series. The division was made into (1) none or practically none, (2) slight to moderate, and (3) marked. This division is necessarily subjective. By following the daily notes carefully the attempt has been made to have the division as accurate as possible. It is impossible to separate slight from moderate in some cases, and so they have been grouped together. Table 1 shows the results.

Morbidity was then analyzed in those cases which had had a test of labor (Table 3).

There were seventy-one cases which had a test of labor. There were forty-four classical sections with three deaths (7.5 per cent). There were twenty-seven low cervical cases with three deaths (11.5 per cent). The morbidity was less following the low type of operation. The details are as follows. In the seventeen afebrile classical cases the record is present in twelve. In eleven, labor was slight. In one case labor lasted twenty-four hours. Two cases had vaginal examinations and two had ruptured membranes (one for sixteen hours, and another for twenty-four hours). The last was also one of the two cases in which vaginal examinations were done. In the fifteen afebrile low cervical cases an opinion as to labor could be formed only in six cases. It varied from twelve to forty-eight hours. The membranes were ruptured in only one case, and in this case they had been ruptured for many

TABLE 1

DISTENTION

	Classical			Low Cervical		
	None	Slight to Moderate	Marked	None	Slight to Moderate	Marked
Total 211 cases	15	117	22	7	41	9

Cases in Labor 48	1	19	8	1	14	5
Classical 28	(4%)	(68%)	(28%)	(5%)	(70%)	(25%)
Low Cervical 20						

No great difference was found in the amount of distention occurring either in the total series, or in those cases that had been in labor.

Morbidity was the second feature analyzed. Any case showing a temperature, after the first forty-eight hours, of over one hundred degrees for twenty-four hours (bi-daily readings) was considered morbid. Table 2 illustrates this factor for the whole group.

TABLE 2

MORBIDITY (WHOLE GROUP)

Classical 303			Low Cervical 133		
Afebrile	Moderate	Marked	Afebrile	Moderate	Marked
185	74	39	95	22	14
(61%)	(21%)	(18%)	(72.5%)	(17%)	(11%)

There was less morbidity in the low cervical group. In the classical group with moderate morbidity one had coryza, two bronchitis, two mastitis, one pyelitis, one sinusitis and six wound infections, one of these resulting in a utero-abdominal sinus which closed two weeks after discharge from the hospital. The same group in the low cervical type revealed two wound infections, and one case of pyelitis. No other possible extragenital causes were found in the morbid groups.

hours. As compared then with the afebrile classical group labor was longer in the afebrile cervical sections.

A comparison of the febrile groups gives the following data. In the classical group with slight morbidity the record is good in three. The membranes were unruptured in all. Two had a twenty-four hour test of labor, and one of these had two vaginal examinations. One had slight labor. Putting against this group the same in the low cervical type, the four cases give data as follows. Three had long labor and membranes ruptured for a long while. The fourth had unruptured membranes, but a forty-eight hour labor and one vaginal examination. In those cases, then, which had slight morbidity, the low cervical group had a longer test and greater incidence of ruptured membranes than did the classical group.

The classical sections with moderate morbidity amounted to ten cases with data for seven. All had a long labor. Four had ruptured membranes, one with a forceps attempt. Three had vaginal examinations. The low cervical group followed by moderate morbidity comprised four with data in two. Both had short labors with unruptured membranes. One of these two had a vaginal examination. In this group, then, followed by moderate morbidity, the two cervical

hours X ray showed large baby (8 lbs 12 ozs) Died one hour after operation. Uterus firm No bleeding Low cervical section (ether) (? cause of death)

13 Primipara. Aet. 21 Funnel pelvis Good test of labor Floating head. Classical section under ether Temperature and respiration elevated next day Definite signs of pneumonia. Died on fourth day of lobar pneumonia of left lung Type undetermined

14 Primipara Aet. 41 Slight labor with one vaginal examination Membranes ruptured four and one-half hours (Baby 9 lbs 7 ozs) Died of diffuse peritonitis on the fifth day Classical section under ether

15 Primipara Aet. 27 Fifteen hour labor Fully dilated Repeated attempts at delivery at home Low cervical section under ether Baby died of cerebral hemorrhage Mother died on the fourth day with diffuse peritonitis

16 Para 2 Aet. 30 Labor lasted forty hours Membranes ruptured thirty hours One vaginal examination. Classical section under ether Still born baby Died on the fourth day of septicemia.

SUMMARY

1 In an analysis of 436 cesarean sections the incidence was 1 in 30

2 Ether was the anesthetic in most cases

3 The gross mortality was 4.6 per cent With the elimination of three patients, moribund before operation, it was 3.9 per cent For 296 classical sections it was 4 per cent, corrected for the above three, to 2.1% For the 133 laparotomies it was 5.3 per cent Fifty per cent of the deaths occurred in toxic patients, thirty per cent in those who had been in labor, five per cent in placenta previa and fifteen per cent in clean, elective, non-toxic patients in good condition

4 No difference in the frequency of occurrence or degree of distention was noted in 208 cases (154 classical and 54 low cervical)

5 The morbidity was less following the low cervical group, both for the whole group and those having a test of labor, but there was little differ-

ence noted in those cases that had not had a test of labor The slight difference was in favor of the low cervical group

6 Neither operation was safe when labor had been long membranes had been long ruptured, and vaginal examinations had been made

7 The mortality in 27 placenta previa cases was 3.7 per cent maternal, and 1.8 per cent for the babies

8 The maternal mortality in 20 eclampsia cases was 20 per cent (corrected 1.6 per cent) Recovery was usually stormy The fetal mortality was 2.5 per cent

9 There were no maternal deaths in 14 cases of separated placenta, 70 per cent of the babies died

10 In 37 cases of toxemia 21.6 per cent of the babies died There were 21 classicals with one maternal death and 14 cervicals with three maternal deaths All deaths occurred in the markedly toxic patients

11 There was a gross fetal mortality of 9.5 per cent

12 There were 203 classical sections in patients not in labor, not toxic and not flowing, 1.1 per cent in sections of elective clean cases in good condition, with no maternal deaths There were 82 low cervical sections in the same class with three deaths (3.7 per cent mortality)

13 There were 93 classical operations in patients who either had had a test of labor were toxic, or had antepartum bleeding with twelve deaths (three moribund before operation) a corrected mortality of about 10 per cent The low cervical operation comprising the same type of case resulted in four deaths in 51 cases (8 per cent)

14 Autopsies were done on two (10 per cent) of the mothers and three (7 per cent) of the babies

15 The individual deaths are summarized

COMMENT

The low cervical section should show less morbidity than the classical in those patients who have had a test of labor However those who have had a long labor with rupture of membranes for a long while, and especially with vaginal examination or attempts at delivery, are not good risks with either operation

The mortality of 1.6 per cent in the cases of eclampsia is lower than some other series, e.g., Gordon¹⁴ with 2.6 per cent, in 104 cases, and Miller¹⁵ with 1.9 per cent in 31 cases. Holland¹⁶ found 3.2 per cent In the 20 cases reviewed by the writer, morbidity was so common and so frequently severe, distention so marked and the recovery so frequently a stormy one, that the mortality might easily have been greater It would seem in view of the lower mortality in eclampsia treated conservatively,

cases only one had been in labor. Another had ruptured membranes for an indeterminate period with two vaginal examinations. In the group with marked fever there was one case of extrusion of the bowels. In the cervical group of fourteen, two cases had been in labor. One of these had ruptured membranes.

Eight of the babies died (21.6 per cent). Four were stillborn. One died of cerebral hemorrhage on the tenth day. Three were premature. The incidence of distention was noted in ten

2 Para 3 Aet. 27 Pregnancy eight and one-half months. B P 160/90, Urine boiled solid. Elective low cervical section under ether. Temperature elevated from the second day. Died on the fourth day from septicemia with no evidence of peritonitis.

3 Primipara. Aet. 26 Hypertension, 175/110. No albumin. Mitral stenosis decompensated. Not in labor. X-ray shows twins. Classical elective section under ether. Died in forty-eight hours of cardiac decompensation with marked vomiting and distention.

TABLE 5
TOXEMIA—37 CASES

Classical				Low Cervical			
Afebrile	Morbid			Afebrile	Morbid		
	Mild	Moderate	Marked		Mild	Moderate	Marked
14 (66%)	2 (10%)	2 (10%)	3 (14%)	9 (64%)	1 (8%)	2 (14%)	2 (14%)

classical sections. Marked distention occurred twice. In nine low cervical cases, marked distention occurred once. The first case had moderate morbidity. The hysterectomy was interesting a few hours after classical cesarean operation the blood pressure fell, the pulse rose and the uterus enlarged. The abdomen was reopened, and a typically apoplectic uterus removed. Recovery was complicated by pneumonia and marked distention.

The degree of toxemia was noted in thirty-three of the thirty-seven cases. In eleven of twenty classicals it was marked, and in eight moderate. Two of the latter were cases of hypertension and valvular lesions with only a little albumin.

The toxemia was marked in five out of eleven low cervical operations, moderate in five, and mild in one. The four deaths all occurred in the markedly toxemic patients, one having in addition mitral stenosis and dying of heart failure forty-eight hours after delivery. Four of the cases could be labeled definitely as nephritic.

A review of these cases shows that there were complicating factors in many instances such as previous repairs, a history of former disasters to the baby, heart disease, transverse presentations, small pelvis, large babies, and sometimes the rapid progress of toxemic symptoms in spite of treatment. Most of the patients were either primiparae or patients who had previous difficult labors. The average age was thirty. Eight babies died, or nearly 22 per cent. Most of these were premature. Many of the mothers were treated for weeks before being delivered.

MATERNAL DEATH REPORTS

A Toxemic Cases

1 Para 2 Aet. 31 Pregnancy seven and one-half months. B P 170/100, albumin and edema ++, in bed for one month. Twin pregnancy with elective low cervical section under spinal anesthesia and enterostomy on fifth day. Died of intestinal obstruction on sixth day.

4 Eclamptic moribund _____

5 Eclamptic moribund _____

6 Eclamptic, primipara. Aet. 30 Elective classical section under ether. Died of hemolytic streptococcal septicemia on the fourth day.

7 Primipara Aet. 18 Eclamptic. Hirst type under ether. Died of diffuse peritonitis, fifth day.

8 Primipara Aet. 28 Membranes ruptured and started in labor because of toxemia. In labor four hours with several convulsions. Patient had grs 9 of sodium amylal, and scopolamine grs 1/150 s.c. at start of labor. Pulse rapid and weak. B P at onset of labor 140. Albumin L T. Classical section under local anesthesia. Enterostomy forty-eight hours later for obstruction. Recovered from obstruction. Ran a septic course with phlebitis of legs and right arm and pulmonary infarct. Transfused seven weeks postpartum, while seemingly on road to recovery developed infarction of left lung and died four days later. Autopsy showed fibrinous pleurisy with tremendous amount of fluid in pleural cavity. Uterus well healed. Old infarct of lung. Old thrombophlebitis veins of broad ligament and saphenous veins.

9 Primipara Aet. 27 Addison's disease and condition poor before operation. Classical section under ether. Became drowsy twelve hours post-operatively with high temperature. Died in afternoon of second day. Autopsy revealed atrophy of adrenals.

THE PREVENTION OF CRIME*

The Gangster In The Making

BY L. VERNON BRIGGS, M.D.

MUCH has been written on the prevention of crime and numerous investigations and surveys have been made in recent years with the object of developing some plan for the reduction of the enormous incidence of crime, especially among juvenile offenders. So far as I know, all this work up to the present time has not resulted in a single dent being made in the crime record, on the other hand there is a continual increase in the numbers of youthful gangsters, with their hold-ups, assaults and murders.

The commissions for the study and prevention of crime which have been appointed by the different branches of our government have usually been composed of people most of whom, having no real experience with the criminal, have had to depend upon evidence presented to them by criminologists, volunteer enthusiasts, one-sided specialists or people with a hobby. This hearsay evidence has then been sifted and a plan formulated for the report, which has usually been pigeon holed and in any case has been of little practical value.

Let us look at this great question in a practical way. Let us discard assumptions, theories and plans for reforming the already hardened criminal and strike at the source from which gangsters and other young criminals develop. It was not until we began to attack the sources of insanity as Dr. Douglas A. Thom has so ably demonstrated in his habit clinics that any scientific progress was made toward its prevention. Any board of health in a community where there is an epidemic does not merely treat the victims of that epidemic and feel satisfied that it is doing all that is possible to protect the community, but it strikes at the source of the outbreak—bad water, impure milk or whatever else.

In the prevention of crime we have never struck at the source in a practical way. Among the hundreds of criminals whom I have examined a very appreciable percentage, old as well as young but especially the young offender of today, began their criminal careers between the ages of ten and twenty, and recently some are beginning at an even earlier age. Many of these young criminals have been well brought up to the time of their school life and they often do well at school, many graduate from the grammar school and some few have spent two or more years in high school. There is no

question of mental deficiency in the majority of these cases. Hundreds of our boys who graduate from grammar school or leave high school before graduation walk out into the world with no prospect of employment and not a soul reaches out a hand to help them. Some of course find employment through the influence of their families or friends or fill vacant positions awaiting such material, but there is a large group who have no friends to give them jobs and whose families, on account of economic or domestic conditions are unable to help them. Discouraged after efforts to obtain legitimate employment and usually being in unfavorable environment they either join the corner gang or get suggestions from moving pictures, radio stories or detailed front-page newspaper accounts dealing with the adventure of crime. Among the boys they meet on the corner are graduates of our so-called "reform schools" (which have proved to be schools for education in crime) who talk over with them the crimes they see depicted in the movies, hear described over the radio or read of in the newspapers, or tell their own experiences as to the easy way of getting money and of the thrills they get from wild rides in stolen automobiles and daring hold-ups. The young gangster as a rule has little interest in safe blowing or house breaking. What most of these boys want is the thrill of adventure, even if there is no financial gain. If caught early in their careers they are usually sent to the "reform schools." A large number among the young criminals whom I have examined were sent at twelve, fourteen or sixteen years of age to one of these schools of crime for appropriating an automobile for a "joy ride" or some other minor delinquency, they have told me that there they met other boys more experienced in crime than themselves, who told them exciting stories about the more serious crimes of hold-up or burglary with whom they planned a life of crime together after their discharge. Some boys make good their escape from the reform schools in order that they may immediately begin their hold-ups and depredations, and so little effort is made to return them to the schools that they are generally free to pursue their avocations until they are finally convicted for more serious crimes.

Another link in the development of the young gangster is the want of classification of these boys after their first arrest. Thrown together with hardened criminals in jails and prisons they listen to the stories of their companions with admiration and a desire of emulation born

Condensed from a paper read at the Fall Meeting of the New England Society of Psychiatry at Butler Hospital, Providence, R. I. October 8, 1932.

*Briggs, L. Vernon—President of the New England Society of Psychiatry. For record and address of author see This Week's Issue page 971.

e.g., Lachenstein¹⁷ 94 per cent, Solomons¹⁸ 103 per cent, Williams¹⁹ 133 per cent and others, that cesarean section should be reserved for those cases where disproportion would indicate the operation regardless of the presence or absence of eclampsia, or for those cases not improving under conservative treatment.

The mortality in the cases of toxemia (108 per cent) is high. The frequent presence of factors such as large babies, previous repairs and so forth made section a necessity in many instances. The fact that warning signals of impending eclampsia were the reason in many cases, and the fact that these symptoms occurred in spite of intensive hospital treatment make us hope that the newer method of Arnold and Fay²⁰ of fluid restriction, concentrated glucose intravenously and so forth will be of greater value than our medical treatment in the past. Moreover, the more frequent use of local anesthesia, in view of the work of Stander²¹, is suggested wherever surgery is necessary in toxemics.

The only death in the placenta previa series occurred from shock due to hemorrhage. The routine presence of a transfusion team ready to operate, in addition to the cesarean team as suggested by Bill²¹ seems logical. Moreover, as postoperative hemorrhage occurred in cases other than those of previa it is logical to have a donor present in every section. This precaution might have prevented some fatalities in the series.

Because of the greater risk when patients have been in labor a long while, it is good obstetrics for the general practitioner to have a consultation with an obstetrician before labor in any case where successful delivery from below is doubtful. The consultant should make a careful obstetrical examination including the use and appreciation of the aid afforded by good x-rays (lateral and anteroposterior) so that, if possible, section may be done as an elective measure, or so that he may with equanimity allow the case to go into labor to full dilatation.

So, too, the poor results of both classical and cervical operations in cases neglected or in labor for prolonged periods with ruptured membranes and vaginal examinations indicate the performance of hysterectomy when the uterus is infected, and hysterectomy, or some form of exclusion, such as exteriorization of the uterus, when probably or potentially infected. The results in this class of case have not been good.

This is not in agreement with other series that have been reported.

The writer wishes to express his appreciation to the Rev. Father Thomas J. Brennan and Miss Josephine Thurlow, R.N., superintendents of St. Elizabeth's Hospital and the Cambridge Hospital respectively, to Charles Kickham, M.D., and James Lincoln Huntington, M.D., the chiefs of obstetrics, to William Haley, M.D., chief of the staff of St. Elizabeth's Hospital, to Sister Elizabeth Marie and Miss Estelle Ord, librarians, and to the members of the staffs whose cases made possible this study.

solutely prohibit children in the formative period of their lives from attending any moving pictures which painted violations of law in attractive colors" He said, "One spring afternoon recently when I passed a so-called 'movie palace' whose front was plastered over with lurid posters advertising the films to be seen there was a film whose hero was a dashing 'two-gun man', one of those thugs that exist only in the movies, rob only the rich and never the poor, are good to their wives and mothers and give dollars to the blind man on the corner Over a space of nearly a block, waiting for the doors to be opened, was a line of several hundred little children, tightly clutching the coins which had been given them by hard-working fathers and mothers. Twenty-five years ago these same children would have spent the afternoon out-of-doors breathing God's pure air

The movies have an infinite capacity for good Some of the great historical films have been masterpieces, but it appears that for every one of these there are ten put out either dealing with sex irregularities or painting crime in rose-colored hues"

The following list of plays is quoted from a single issue of a Boston paper some time ago, today you will find them similar and even more startling "Her Man," "Love in the Rough," "Doorway to Hell," "Sm Takes a Holiday," "Lady of Scandal," "The Big Pond," "Derelect" "Feet First," "Mm and Bill," "A Lady Surrenders" and "Scarlet Pages", and this after a new code of movie conduct had been ratified by the Directors of the Motion Picture Producers and Distributors of America Inc! "The Code," an announcement said "will determine the character of motion pictures exhibited in 22 000 theaters in this country Among other provisions scenes of passion shall not be introduced when not essential to the plot (1) The sanctity of the institution of marriage and the home shall be upheld. Crimes against law shall never be presented in such a way as to show sympathy with the crime as against law or justice Acts of murder or brutality shall only be presented in such a way as will not inspire imitation, methods of crime shall not be presented in explicit detail on the screen, revenge in modern times (1) shall not be justified as a motive" Anyone who attends moving picture shows will be surprised at the interpretation of the code shown in the films put on by this body of directors

The *Boston Record* of May 1, 1933, printed a dispatch from Hollywood describing a new film "Miriam plays the prim welfare woman's daughter, who rebels against repressions and steps out to taste life Frederick will be seen as the man-about-town who helps her dig out what a young girl shouldn't know, Ralph plays a crook again, this time a petty larcener, who invites much sympathy and dies in the end."

A radio in one of the daily papers of "The

Townsend Murder Mystery," reads "Butler shot as he answers telephone—New tragedy of Townsend home claims Quintus Jones as victim—Detectives, rushing to the spot, find Jones lying by telephone in a pool of blood," etc

An interesting page appeared in *Life* February 22, 1930 A hold-up man is pictured as having just shot and killed his victim Above this pair is an advertisement of various popular makes of pistols for sale by a mail-order house in Denver, Colorado

If the radio, and especially the moving pictures are not responsible for the education in crime of children under ten years of age, I should like someone to tell me how some of these youngsters get the information which they use so effectively to carry out crimes requiring a knowledge and skill which it would be impossible for them to have without some suggestion or information I have made inquiries into the cases of a number of very young criminals and have obtained their photographs, for study, I refer briefly to a number of these

F R, aged 12, was indicted in Nashua, N H, in 1928, for murder in the first degree, having killed another child of 9

Two little brothers, aged 5 and 7, confessed to the murder of a three-year-old baby in 1929 After mutilating and killing the child, they buried the body

In East Boston in 1926, three boys of 9 and 10 killed a five-year-old companion and threw his body into a pool of stagnant water after stripping him of his clothing

In September, 1929 two boys, aged 9 and 13, buried alive a companion of 11 When dug up the victim was found to have a bullet hole in his body These boys were tried for manslaughter

In Paintsville, Kentucky, on April 2, 1930, a reform school boy, aged only 6, was convicted of manslaughter for slaying a child of 8, after an altercation over a piece of scrap iron which the two had sought to sell to a junk dealer

In July 1929, D N, aged 8, of Elizabeth, N J, was paroled having slain his brother aged 16, with a rifle, after a quarrel over the rifle

In January, 1932, S W, aged 14, slew a farmer for whom he was working in Norristown, Pennsylvania He said that he shot his employer in order to get an automobile to go and see his mother, who was ill—a typical case of the result of suggestion from some source as to how to gain his end.

On November 2, 1931, P S, aged 7, of Union, N Y, shot and killed his sister because, he said, she teased him and spoiled his spelling book

A few years ago a careful investigation was made in New York City of the space given to crime items in twelve of the leading newspapers The sum of such items for a month in these twelve papers was 4,712, covering 89,862 inches of space The percentages of crime news in relation to the whole varied from 11.87 per

of a natural love of adventure. I once questioned a thirteen-year-old boy whom I saw walking in the yard of one of our jails in company with an extremely tough-looking inmate. He told me he was there for stealing candy and cigarettes and expected to go to court the following day. Of his companion he said, "Gee, he's a great guy! He's been in prison many times. He has been telling me of his robberies. He has killed two men in his getaways. Gee, he's a great man!"

More than a hundred boys between fourteen and sixteen years of age are held in the Charles Street Jail every year and nearly as many in the Middlesex County Jail at East Cambridge, almost all of whom could safely be released while waiting for a hearing, according to Mr. Alfred F. Whitman, Ex-Secretary of the Children's Aid Association.

I wonder why so many young people of today are more interested in crime and criminals than in the prevention of crime? Is it the exploitation of crime through our modern channels which reaches every home in our land and which makes the gangster the hero of many susceptible young minds?

I cannot here take up the question of the lack of institutions or of any special provision for the scientific care and reform of this group. My present subject is prevention, that is attacking the causes of crime at its source and protecting these boys from the temptations of an environment which educates them in crime and gives them the desire for such thrill and inspiration as it provides. We know how ready and even eager the communities and even the legislatures are to punish these young offenders after they are caught and to provide the money to pay for their different arrests, their trials and temporary segregations where they are fed and clothed and often reeducated for further deeds of violence at great expense to the taxpayers. We know of the many associations and societies whose object is the reform of criminals, and the different welfare organizations which contribute to the support of their families but pay little attention to the prevention of delinquencies.

My plan would be for all these organizations or the communities which they represent to get together and form a personnel to be on hand when these boys graduate or leave school prematurely, to take them by the hand and guide them into normal pursuits. Such organizations throughout our states would cost less by many thousands of dollars than we now spend for the care of these individuals in after-life and would prevent an untold loss of life and property from depredations, hold-ups and burglaries, and it would add to the number of useful citizens who can take care of themselves, instead

of forcing us to employ detectives, police and afterwards wardens at great expense, to watch over them for the rest of their lives.

When a boy is obliged to leave school, for whatever cause, a blank questionnaire should be furnished him to fill out which would inform the teacher what plans or desires he may have for the immediate future. If the reply shows that arrangements for him have not already been made, his questionnaire card should be turned over to the members of the follow-up organization, in whose hands the boy should be placed until they are sure that he is protected from dangerous influences and has a proper place in the community.

I agree with Professor Francis B. Sayre that the accepted methods of our day are not materially reducing crime and that prevention should begin with the child in the school. But I believe that the next step is to care for these young people the moment they leave school, by providing them with friends who will extend to them a helping hand, assist them to find employment and prevent their being led into lives of crime. Some plan such as I have suggested for helping the group who are now lost to the community because of neglect after leaving school should certainly be available, in addition to what is being done in the school. One would have to go farther than Professor Sayre's progressive program.

More than this, something effectual should be done to remove the continual suggestions of crime which come to children in nearly all classes of life from their earliest years. I believe that a campaign should be started to educate our censors of moving pictures, radio stories, etc., to the serious dangers of crime pictures and stories, which are probably now the cause of much crime in the State. Many of the young gangsters have told me that when the gangster business was dull and they were not meeting with much success they went to see crime pictures, to be "pepped up" and get inspiration and encouragement and to learn new methods for their work. They don't mind whether the story has a moral and the burglar is caught and punished, that does not interest them. What they want are the details and the mechanism of the crimes. They will tell you what the celebrated "Lone Wolf" told me when I asked him why, with his education and background, he was willing to take up his "profession", as he called it, of crime. He answered that it was because it was so lucrative and safe, he had studied statistics and found that 80 per cent of the criminals never were caught, and that of the remaining 20 per cent only four or five were convicted, he said it was "a dead open and shut gambler's chance."

Attorney General Bushnell some years ago urged the enactment of a law which should "ab-

rest. He left school at 15 and entered a manual training school for evening study, but spent three nights out of every five with girls at moving picture shows. He was one of those boys who enjoy thrills which he began by speeding his automobile around corners on two wheels. He and another boy stole \$700 in Liberty Bonds and \$50 in cash from a safe in his father's room and he also took his father's automatic revolver. He said, "Every movie I saw which showed what happened in the West always had a revolver in it. With the revolver and the money he went to a hotel in Springfield, flashed his revolver about and behaved generally like a bad man from a Western movie. Followed to his room and questioned by a policeman in plain clothes he asked the latter to telephone his father and on his return he pointed the revolver at him and told him to get out and as he refused to do so the boy shot him in the breast. He then telegraphed his father that he had 'shot a bull' and boarded a train for Boston. On the train he continued bragging and displaying his revolver and telling the other passengers that he had 'shot a bull.' A policeman finally boarded the train to arrest him and the boy fired several shots at him from which the officer subsequently died.

Another young murderer whom I examined was C. T. aged 19 of Italian parentage the fourth of nine children. His father was cruel to him and when

he married a second wife all the children of the first wife left home. The father said that he played truant while he was in the sixth grade in school, but there is no record of this in the school, the teachers reporting that he was "a well-conducted boy, who never gave any trouble, noted for his very polite manners and good nature." Like all of his brothers and sisters he left school as soon as he was of working age but got no employment that gave him a regular wage. The Society for the Prevention of Cruelty to Children and the Associated Charities were both appealed to in his case but he was nevertheless allowed to drift into a criminal career. At 14 he attempted larceny and was committed to Shirley. Later he was again committed to Shirley and afterwards paroled; after this he committed a robbery in Ashburnham and defaulted on bail of \$2,000, and still later he was found guilty of breaking and entering a store in Fitchburg. Finally he committed a murder and was executed before he was 20.

In the hundreds of cases cited in the daily press and many whom I have examined I have found that nearly all of them show the necessity of such work as I have suggested to keep these boys away from evil associates and suggestions on leaving school, and to prevent their drifting into lives of crime.

ATRESIA OF THE CERVIX ASSOCIATED WITH HEMATOMETRA

BY EUGENE E. ALLEN, M.D.*

FOLLOWING is the report of a case of unusual interest which has recently come to my attention, and of which there is little found in the literature relating to the subject.

In the *Medical Journal of Australia*, dated August 6, 1932, I. Graham of New South Wales, describes a case of hematometra and uterine maldevelopment. In his case which is similar to mine, the cervix was found undeveloped and the uterus contained chocolate-colored blood.

History. A white female patient, aged 15 years entered the Massachusetts State Infirmary complaining of pain in the lower abdomen and back, associated with an abdominal mass.

Her past history was essentially negative except for the fact that she had never menstruated.

The family history is irrelevant.

Present Illness. Five months previous to her admission she began to have cramps in the lower abdomen, associated with a sharp pain in the lumbar region. These pains lasted for three days. The pains occurred regularly each month until the time she was admitted. In the last two attacks the pains lasted for one week each time. At no time were there any signs of blood. Four months previous to her admission a mass appeared in the left lower quadrant. Each succeeding month the mass was larger and was associated with more or less continuous lower abdominal pain. Nausea, vomiting and dizziness always accompanied the attacks. She sought advice at another hospital and was examined under ether. The diagnosis at that time was re-

tained menses due to atresia of the vagina. She was referred to our hospital for hysterectomy.

Physical Examination. On physical examination the patient appeared fairly well developed and nourished. She weighed 95½ pounds and was five feet in height. Her usual weight was 104 lbs. Her carriage was erect. The temperature was 99.6°, the pulse 84 and the respirations 22. Mentally she appeared normal. The tongue was moist and protruded in the midline. All the teeth were present and in good condition. The mouth was clean. The tonsils were hypertrophied. There was considerable acne of the face, chest and back. The reflexes were normal. The color of the hair was light brown. The eyes reacted to light and distance, their color was blue. The breasts were normal, virginal in type. The heart and lungs were normal. On abdominal examination the fundus of the uterus was found to be enlarged to within two fingers of the umbilicus and freely movable. The abdomen was dull to percussion. No sounds were heard by the stethoscope. No fetal parts were felt. There was tenderness on palpation and the abdominal recti muscles were tense.

Vaginal Examination. Normal nulliparous genitalia. The introitus admitted the tip of the little finger.

Extremities were negative. Blood pressure was 118/72.

Laboratory findings were negative. Under ether a small Sims speculum was admitted. A very slight leukorrhea was present. On the floor of the vagina and running the length of it was a mound of tissue about 3 mm. in height. The vaginal canal was about 6 cm. long. There were no vaginal fornices. Instead of a normal cervix with an os there was a small thickened circular area about the size of a quarter. Bimanual examination showed the uterus

Allen, Eugene E.—Senior Physician, Female Hospital, State Infirmary, Tewksbury, Mass. For record and address of author see *This Week's Issue*, page 971.

cent in the *Evening Telegram* to 33.11 per cent in the *Daily News*. The survey was made four years ago and items of this nature have greatly increased since that time.

The court rooms in our cities are also schools for criminals. Youths bent on a criminal life can learn the methods of old and experienced wrong doers in the court room. In notorious cases, especially hold-ups with a lot of thrill in them, you will not only find the court rooms crowded with gangsters in the making, but the corridors adjacent to the court rooms are also filled with persons anxiously awaiting a turn to get in and learn the intricacies of the trade of the safe blower, the artful methods of the hold-up man and the cunning of the murderer who puts his victim "on the spot." One of our Deputy Commissioners of Corrections says, "When I was in Court the other day I learned how to break into a safe, the names of the chemicals, the electrical tools and other articles used by safe-blowers." I again quote District Attorney Bushnell. He says, "I'd like to see the Court, in a rotten case, bar the doors and search everyone in the courtroom, and it would be surprising to see the number of fellows there who have records."

I feel sure, after all these years of experience, that if these evil suggestions could be removed or even partially controlled, and if an organization could be perfected by the State or by the communities therein, to give a friendly hand to these boys at the time they need it—which they virtually never receive today—instead of the unlimited attention paid to them later, it would be only a few years before we should see a lowering of the incidence of crime in Massachusetts. Only by such means, by attacking crime at its source, can real prevention be brought about. As the State now looks after the defective eyes, teeth, etc., of our school children, let it also look after their morals and the future of the comparatively few graduates and those who have to leave before graduation who are without friends or moral guidance at the most critical period of their lives.

The following brief summary of some typical cases of young criminals whom I have personally examined among thousands which have come to my attention will illustrate my subject.

H. J. G., aged 20, whom I examined in prison came of a family well known to the leading social agencies, including the Family Welfare Society, the Little Wanderers Home, The State Minor Wards, the Children's Mission, the Jamaica Plain Emergency Loan, the Lowell Social Service Exchange, the Brookline Court, the American Red Cross, the Children's Aid, the Provident Association and the Women's Educational and Industrial Union. All of these agencies were in touch with the family for several years but I cannot find that any steps were taken to prevent this boy's becoming a criminal. He left school at 14 to go to work, having finished the sixth Grade and started the seventh. He joined a corner gang called the "Dirty Dozen" and spent much time

with his companions loafing on the corners, going to dances and the movies in the evening. He was characterized as the "Baby faced Robber," and was finally electrocuted for first degree murder, having shot and killed a Medford storekeeper during a hold up.

A. F. D., aged 17, S. B. T., 18, and J. R. S., 17 were examined by me following a series of burglaries which ended when their car, loaded with loot, was held up by a policeman whom they shot dead. All were indicted for murder in the first degree and convicted of murder in the second degree. Of these boys, A. F. D. began his thefts at 6 years of age. At 13 he made the acquaintance of a boy of his own age, H., who had escaped from the Lyman School, and they made a break which resulted in their both being put on probation. In spite of this, he is reported to have graduated from grammar school when 15 years of age with a "good record no trancies and no tardiness." In the same year he was sentenced to five years at the Shirley Industrial School, but was again put on probation.

The second of this group S. B. T., finished the sixth grade at the D. School when 16 years of age, his intelligence quotient is given as 83. Neighborhood influences were bad, as in all these cases. The head master of the school, nevertheless "thinks he was a good boy up to the time he left." He really felt that "the boy was waiting for someone to hand him a job" which of course nobody did. He managed to get a radio, a crystal set. In fact these three boys were so much interested in radios that they never missed an opportunity to steal a radio from any house that they robbed. S. B. T. was a member of a gang of which his two companions and H. were also members.

J. R. S. the third of the group left school at the age of 15 after completing the sixth grade. His family had been helped by the Elliot Church the Associated Charities, the Overseers of the Poor, etc. He told me that he had little amusement in his life excepting from the movies which he had begun to attend at the age of 11. He said "I liked series of pictures, that I followed up. Saw Lon Chaney Hundoz Bum (?) Phantom of the Opera etc. His reading for the last six years had been confined to detective stories, 'especially Flynn's'."

I examined S. Z., aged 17 following his arraignment for the murder of a fourteen-year-old girl he had committed many other serious delinquencies. He said that he began stealing candy and breaking into small shops at the age of 10. He was arrested several times for truancy and was sent to the Hampden County Training School but ran away from there. At 14 he was arrested for breaking and entering and sentenced for two years to the Shirley School. In spite of his having previously run away three times from reform schools and staying out once for as long as four months before he was caught, and in spite of his previous record at the Hampden County Training School and of his staging a movie wreck which was discovered only in time to prevent disaster on the Boston and Maine Railroad he was considered by the authorities of the school for discharge into the community with the belief that he would do well. Up to the time of his residence in these "reform" schools he had been guilty only of truancy and petty delinquencies when he escaped he continued his delinquency and spent most of his time with a gang of boys and girls. His reading had been confined to accounts of murders and other crimes in the newspapers.

I examined F. W. P. aged 19 after he had been confined for more than a year in jail awaiting trial for shooting a policeman in an effort to avoid arrest.

CASE J R. Operated August 4, 1928, at the Boston City Hospital.

The incision is made on the lateral aspect of the arm over the middle third and over the insertion of the deltoid. The long head is dissected out. A Kelly forceps is then pushed beneath the deltoid and pulled down toward the insertion. The ruptured tendon of the long head was then pulled under the insertion of the deltoid and the tendon then sutured to itself and to the insertion of the deltoid.

The patient returned to work after six weeks.

CASE J D. aged 49 yard worker for a paper company. Seen March 9 1931. He was lifting a log of 50 to 75 pounds when the right arm gave way. This was in January. He kept on at heavy work, then at light work until recently but had to give it up.

He was operated on at the Faulkner Hospital, March 11, 1931. Typical operation. The torn tendon was carried through under the deltoid inser-

tion. He made a prompt recovery, and the stitches were out after nine days. He was discharged April 2, 1931.

This patient, a small man of phenomenal muscular development, went at hard work promptly after three weeks, and the muscle hitch stretched a bit.

A second operation was done October 2, 1931, at the Faulkner Hospital. An incision was made through the scar. The hitch in the deltoid insertion had held, but probably had not been made short enough. At all events the outer head was slack. Fascia was used to take a reef in the muscle and tendon and he was kept in the hospital thirty three days to make sure.

This time it held with a really restored muscle.

In no other case has there been slackening, or any loss in the effectiveness of the mechanical hitch in operations under this technique in a not inconsiderable total of cases.

ABSTRACTS OF DR. CAMPBELL'S LECTURE

Charging that psychiatry has devoted too much of its energy in recent years to the classification of psychiatric cases into neat and arbitrary types, Dr Charles Macfie Campbell, Professor of Psychiatry, Harvard University, in his second Salmon Memorial Lecture delivered April 20, 1934 at the New York Academy of Medicine called for an 'arbitrary respite from this activity' and urged the medical profession to concentrate 'on the dynamic analysis of psychiatric problems and cases'.

'One of the most important advances in psychiatry,' said Dr Campbell, 'has been the fuller realization of the importance of the personal factor in the psychiatric case'.

The interpretation of the psychosis as a maladaptation and as a miscarriage of an attempt by the patient at a solution of his problem, instead of as a meaningless disturbance has according to Dr Campbell, advanced psychiatry both in its interpretation of the material it deals with and in its curative effects.

Dr Campbell urged that the psychosis the specific form of the patient's psychologic difficulty can be, and should be studied as one section of the individual's life history, from which much understanding, both as to the nature of the individual and of his case may be derived.

In studying the psychosis it is much more important that the component elements be identified and understood than that they should be identified under conventional names.

The concern with classification and labelling of cases Dr Campbell believes interferes with the appreciation of the dynamic nature of psychiatric problems.

A convenient classification of psychiatric cases can be achieved under the headings of organic, toxic and symptomatic psychosis. In some of these

divisions the impersonal factors play a prominent part in bringing on the psychosis. A certain number of patients too can be classified according to specific types of vulnerability and their 'breakdown' can be explained in terms of their weaknesses and the particular strains to which they were subjected.

There is left, however even after such classifications, a large residue of rather serious cases which accumulate in the psychiatric hospitals and which constitute a serious challenge to the psychiatrist. In this residual mass are to be found the dementia praecox or the schizophrenic cases.

Dr Campbell reviewed the question as to whether the dementia praecox group represents a type of psychiatric case in which an impersonal disease process is operating.

He expressed the opinion that the intensive study of cases belonging to this group has not enabled one decisively to demonstrate the presence of an impersonal disease process revealed either by clinical symptoms or by histopathology.

FOUR INSTRUCTIVE PAMPHLETS

The Metropolitan Life Insurance Company has for distribution four pamphlets dealing with the family food supply, suggestions for good food at low cost, the baby, and diphtheria prevention.

A physician may use these brochures to advantage when it is desirable to provide his patients with concise information in these subjects. The importance of consulting a physician whenever there is evidence of departure from the normal is made clear.

If every pregnant woman would study the pamphlet on The Baby or some equally good publication, both the mother and her child would profit thereby.

fluctuant and enlarged to about the size of a four months' pregnancy. No masses were felt in either vault. Ovaries and tubes were not palpable. It was felt that something could be done to save this patient for possible childbearing and not subject her to the serious operation of hysterectomy. Consequently she was operated on in an attempt to construct a patent uterovaginal opening. An incision was made in the center of the thickened circular area described. Goodall & Hanks' dilators were used to enlarge the opening. A thick chocolate-colored blood oozed out, estimated at about 1000 cc. Her convalescence was uneventful. Later examination showed that the opening had closed. She then developed an acute attack of tonsillitis. Following this complication she again experienced what were probably the symptoms of menstruation and it was found that the uterus was again becoming distended.

Again she was taken to the operating room. This time the uterine cavity was entered in the same manner as before and the inner and outer edges of the opening drawn together with catgut sutures. About 500 cc of thick mucilaginous like dark red blood was expressed. A number 24 soft rubber catheter was fastened in situ, being removed the following day. Her convalescence from this operation was rather stormy as the vaginal discharge became somewhat purulent and the temperature rose to 103°, with a white cell count of 22,000. She was

given appropriate treatment, but with the subsidence of this complication the tonsillitis, which she previously had, recurred. She gradually overcame this complication. Vaginal examination again showed the uterovaginal opening to have closed and once more, five weeks following the second operation, she was removed to the operating room and a modified Pozzi operation was done, the incision being stretched to about 1½ inches in diameter. About 30 cc of a foul smelling purulent sanguineous fluid oozed out. Iodoform gauze drain was left in situ for twenty-four hours. Convalescence was fairly good, the temperature going occasionally as high as 102°. Seventeen days after operation she was given potassium permanganate douches and sitz baths. Examination showed a patent os with no discharge or tenderness. The patient felt well and was up and about the ward. Since the last operation, she has had two normal periods while in the hospital, staining seven pads each time. Her weight on discharge was 112½ lbs. She had a tonsillectomy and adenoidectomy done following the third vaginal operation, and now feels perfectly well.

Since her discharge from the hospital, I have had two communications from her, one by letter and one by a visit and she has had two more normal periods, each time experiencing only slight discomfort.

RUPTURED BICEPS TENDON REPAIR

BY FREDERIC JAY COTTON, M.D.,† AND GORDON M. MORRISON, M.D.†

RUPTURE of the biceps tendon is not at all unusual. Nearly always it occurs at or after middle age. Rarely the tendon leading to the radial insertion gives way. This I think always occurs before fifty from major trauma, i.e., lifting. The picture is unmistakable, see figure 1. Repair is by direct tendon suture. I have operated on one case, which did well, but no end-result report is available.

Far commoner is the rupture of the long head, which gives way in a lift not always heavy, in an elderly laborer without previous recognized disability. The rupture is not that of a normal tendon, but of one worn and atrophic as the structures about the shoulder so often are in age*. The picture is typical and constant, see figure 2.

The break may occur at any point above the muscle belly, but commonly in the bicipital groove, often within the shoulder joint. The reaction is slight, often disregarded. The disability is definite in weakness, but often not conspicuous. Save for the ease of complete repair, the operation might often be debatable.

Much type has been wasted in discussing fixations by suture in the groove, or even through the drilled shaft. The matter is really almost ludicrously simple. There is one absolutely solid

RUPTURE OF BICEPS TENDON

FIG 1 Upper left. Typical rupture of the long head.
FIG 2 Upper right. Rupture of the tendon below the muscle belly—a rare accident.
FIG 3 Lower left. Rupture of the long head. Coiling up of the snapped tendon into the muscle.
FIG 4 Lower right. Tendon passed through the deltoid insertion back to the outer muscle belly into the mass of which it is sutured. The appropriate tension on tendon and muscle must be a matter of judgment.

ANNOUNCEMENTS

All meetings will begin promptly Standard Time

Every member is requested to register and receive a badge before entering the General Assembly Hall Please present your membership certificate when registering

During the discussion of papers, the speakers will please announce their names plainly for the benefit of the stenographer and then walk forward to the platform so that the audience and the stenographer may plainly hear what is said

Discussion of papers is open to all members and guests of the Society It is not limited to those named on the program

Ladies of visiting members are cordially invited to visit Manchester during the state meeting and are urged to attend the entertainment on Tuesday evening and the banquet on Wednesday evening

Members of the resident Ladies Committee will be in attendance at headquarters to render such services as may be desired by the visiting ladies

As heretofore the usual exhibition of x-ray apparatus books surgical appliances drugs and foods will be held Application for space should be made to Dr George F Dwinell, Manchester

GENERAL MEETING

TUESDAY, MAY 15, 10 A.M. S T

Call to order by the President, Robert J Graves, Concord

Invocation, Rev Erville B Maynard, Rector Grace Episcopal Church, Manchester

Address of Welcome, The Mayor, Damase Caron, MD

Report of Committee on Arrangements Howard A Streeter, Chairman Manchester

Prolapse of Uterus During Pregnancy Donald E Higgins, Epping

NEW HAMPSHIRE MEDICAL SOCIETY

THE ONE HUNDRED AND FORTY-THIRD ANNUAL MEETING

Hotel Carpenter, Manchester, N. H.

Tuesday and Wednesday, May 15-16, 1934

ALL meetings will be called to order promptly at the stated hour—Standard Time

The first meeting of the House of Delegates will be held Monday evening, May 14, at 7 30 o'clock, Hotel Carpenter, and subsequent meetings will be in the same place

The Scientific Sessions will open promptly at 10 00 o'clock A.M., Tuesday, with General Meetings forenoon and afternoon, Tuesday and Wednesday

Wednesday evening, May 16, Banquet 6 30 o'clock, Hotel Carpenter Tickets, \$1 50 each

OFFICERS FOR 1933-1934

President

F M PAINTER, A.B., ASSISTANT EDITOR

CASE 20181

PRESENTATION OF CASE

A sixty-seven year old American widow entered the Massachusetts Eye and Ear Infirmary for treatment of a cataract in the right eye

Eighteen years before admission while in San Francisco she was found to have sugar in her urine and a blood pressure of 190 Since that time she had been on a slightly restricted diet She tested her urine about once a week and found the reaction was usually green, rarely blue, and not infrequently red Twenty-one months before admission she was awakened one night with severe vertigo She got up for a short while but returned to bed on her hands and knees, still very dizzy The next day she could not get up because of these symptoms Her physician gave her several injections of insulin Her blood pressure at that time was 260 She was in bed for about three weeks during that episode, but had no further recurrence A few months after this attack an ulcer appeared on her right great toe One year before admission she had a cataract removed from her left eye

Family history Her mother died of pneumonia, her father of heart disease at the age of seventy-two There was no history of tuberculosis, cancer or diabetes

Marital history She was married twenty years before entry Her husband died three years later from ulcers of the stomach She had never been pregnant.

At the Eye and Ear Infirmary a cataract was removed from her right eye She did well until the fourth day after operation, when she began to vomit, complain of thirst, and become very restless A medical consultant found that she was dehydrated, had an acetone breath and appeared on the verge of coma Her urine showed a brown test for sugar Two preceding tests had been negative She was given a clysis and put on insulin by test On the fifth postoperative day she complained of some pain in her left chest Her temperature rose to 100.4° and on the following day râles were found at the left base Her blood pressure was 220/110 on admission to the Infirmary

On the sixth day she was transferred to the Massachusetts General Hospital

Physical examination showed a well developed and nourished woman lying in bed, moderately orthopneic The skin was dry There was an eye shield over the right eye The left eye showed the result of an old cataract operation The mouth and tongue were dry The thoracic expansion was limited because of inspiratory pain over the precordium and the left axilla Over the lower half of the left chest and in the axilla there was a fairly definite coarse friction rub There were also many coarse râles There was no dullness or change in whispered and spoken voice The abdomen was moderately distended and tympanitic The liver was felt two fingerbreadths down The heart was not enlarged to percussion. The sounds were weak and regular No murmurs were heard The blood pressure was 140/90

The temperature was 103°, the pulse 118, the respiratory rate 32

Examination of the urine showed a large trace of albumin, a green test for sugar, and no acetone Examination of the blood showed a red cell count of 5,800,000 with a hemoglobin of 70 per cent and a white cell count of 24,900, with 88 per cent polymorphonuclears The fasting blood sugar was 133 milligrams, the carbon dioxide combining power 52.5 volumes per cent

For the first few days her general condition improved slightly and the temperature went down to 101° She was uncoöperative however and required large amounts of sedatives On the fourth day in the Massachusetts General Hospital her condition became definitely worse She was mentally confused, screamed, moaned, groaned, twisted, and tried to get out of bed almost constantly She fell out of bed on one occasion without apparent damage There were moist râles up to the midscapular region on both sides, more marked on the left The urine tests were blue for the most part, with an occasional green test On the fifth day she was observed to have complete left hemiplegia She was conscious but was unable to speak. On the sixth day her pulse and respirations were considerably elevated She became comatose and died on the following day, eleven days after operation

DIFFERENTIAL DIAGNOSIS

DR DWIGHT L SISCOE This seems to me a very complicated and very difficult situation. I approach it with a little more temerity perhaps because of the difficulties of pathologist and clinicians in the last case

Here is a sixty-seven year old widow who we are told had hypertension and diabetes of eighteen years' duration, both of which statements we have to accept at their face value She came to the Eye and Ear Infirmary for a cataract operation It was done and nothing happened until four days later, when she developed pain in the left chest and had some difficulty with

thing, perhaps uremia, perhaps septicemia. I find it very difficult to know which to say. Those symptoms were followed by falling out of bed, and the morning after that by complete hemiplegia. One wonders if she injured her head and skull in falling out of bed. That might have caused a cerebral hemorrhage or have ruptured a vessel or an aneurysm that might have been there from an old luetic lesion. I do not know.

The urine test was still blue and the diabetes was definitely controlled, so that I think we have no diabetic problem here. I feel that although this woman died in coma, it was not diabetic coma, or in my opinion uremic coma. We are not told the non-protein nitrogen figure. On the whole I feel that her comatose condition at the time of death, with left hemiplegia, was associated with cerebral hemorrhage, possibly preceded by a thrombus or an embolus which may have come from a coronary infarct with thrombosis.

The other diagnoses are of course diabetes, which I accept at its face value. She had a cataract, and hypertension of at least eighteen years' duration. It might have been essential in type. Coming on at forty-eight years of age with the diabetes and obviously arteriosclerosis, I think it was more probably not essential in type.

I cannot escape the feeling that this woman had a definite infection, possibly streptococcus septicemia, perhaps only an infection following a coronary or pulmonary infarct.

DR TRACY B MALLORY: Have you anything to add, Dr Brailey?

DR ALLEN G BRAILEY: I saw her during one day in the Eye and Ear Infirmary. It was perfectly evident that she was mildly psychoneurotic. In regard to the cerebral symptoms she had always been an extremely difficult patient. When she was there four years earlier she rushed about the ward and was extremely temperamental. The following morning she had a clysis, fluids and orange juice, and was straightened out. The following day she had pleurisy in her left axilla, not very severe, a few râles, a little fever, and a fall in blood pressure. As I remember, her blood pressure was not over 200 and she had a drop to 150, and I am afraid I passed it off as a drop in blood pressure due to rest and sedatives. I thought she had infarct of the lung or pneumonia when I sent her to the Massachusetts General Hospital.

CLINICAL DIAGNOSES

Cerebral hemorrhage from arteriosclerosis
Hypertension
Diabetes

ANATOMIC DIAGNOSES

Thrombosis of the right circumflex coronary artery
Cardiac infarction with perforation of aneurysm, left ventricle
Hemopericardium
Cardiac hypertrophy

Occlusion of right middle cerebral artery (embolism? thrombosis?)
Cerebral infarct, recent
Cerebellar infarct, old
Hydrothorax, bilateral
Pulmonary fibrosis, right, middle
Chronic pleuropericarditis, right middle lobe
Arteriosclerosis marked coronary, slight aortic and renal, cerebral
Perihepatitis
Pernisplenitis
Cyst of parathyroid
Obesity

PATHOLOGIC DISCUSSION

DR MALLORY: The autopsy showed a very large infarct of the heart which was due to closure of the right coronary rather than the left. In the central portion of the infarct was a definite aneurysmal bulge, and evidently as the final terminal event this cardiac aneurysm had ruptured, she had 300 cubic centimeters of blood in her pericardial cavity. Overlying the infarct in the heart was a thrombus and presumably from this a small plug had broken off and filled the middle cerebral artery, so there was a large area of softening of the brain.

It is rather difficult to guess at time factors. She must have had the infarct and the aneurysm for a considerable length of time, obviously long before the operation for cataract, and I should imagine that the rupture of the heart was terminal, probably subsequent even to the cerebral embolus. I can hardly imagine she could live very long with that amount of blood in the pericardium.

DR SISCOE: Did you find any evidence of lues in the aorta?

DR MALLORY: No. There was nothing definite there.

DR CHARLES S KUBIK: There was also an infarct of the cerebellum, which probably accounts for the vertigo a year and a half or so before her death.

CASE 20182

PRESENTATION OF CASE

This is the case of a forty-four year old Negro steward. Seven years before admission he was refused a life insurance policy because of hypertension. About this time he began to have very severe headaches, usually in the morning. Five years before entry he first noticed dyspnea on exertion and felt generally run down. His appetite remained good and he lost no weight. Two years before admission the dyspnea increased considerably and he was forced to use two or three pillows at night. Occasionally he was awakened at night by asthmatic attacks which lasted fifteen to thirty minutes. He noted that his feet were frequently swollen. He attributed this to his work, which kept him on his feet. A year before entry he was obliged to give up his work because of weakness and dyspnea, and at this time he noticed feeling

sugar in the urine. She was transferred to the Massachusetts General Hospital, where temperature developed and later she died with symptoms which suggest a cerebral accident of some sort.

Of course the interesting thing to me was that twenty-one months before admission she had an attack of vertigo, apparently a very severe one, obliging her to go back to bed on her hands and knees and necessitating staying in bed for three weeks. The most logical assumption would be vascular arteriosclerosis associated with hypertension. I think she probably had more or less arteriosclerosis, because a diabetic of eighteen years' standing would be likely to have arteriosclerosis. Lues must be considered as a cause of the vertigo. The fact that she had diabetes makes us wonder if she had a hypoglycemic reaction. She had not taken insulin before. I have never seen hyperglycemia per se cause vertigo. I think the fact that the doctor gave her insulin following this attack does not necessarily mean that hyperglycemia caused the vertigo. Of course alcohol or nicotine causes vertigo, although we have had no information about either of these. Her blood pressure was said to be 260. I believe we are perfectly justified in assuming that this vertigo is vascular and hypertensive in type.

When she was taken to the Eye and Ear Infirmary for operation on the cataract we have no statement about her cardiorenal vascular system other than that she had a blood pressure of 220/110. I think the cataract was not connected in any way with the vascular system, because she went along very comfortably until the fourth day. I am assuming it to be a senile cataract. It may possibly have been a diabetic one.

On the fourth day she began to vomit and complain of thirst and became very restless. In the presence of a statement of diabetes, vomiting, thirst, and later dehydration and acetone breath, of course diabetic acidosis would be the first consideration. On the other hand there are other possibilities in that syndrome. Those symptoms may be related to intracranial pressure of some sort, or possibly to an infection. The onset of infection, especially septicemia, might cause such a syndrome. Perhaps dehydration alone would do it. On the whole I am inclined to interpret this as due to diabetic acidosis, although we have no carbon dioxide figures at that time.

Then we come to what was to me the chief stumbling block in this case, pain in the left chest. We are not told about the character of the onset of this pain. I do not know how persistent it was. One immediately thinks of all of the things that might cause pain in the chest and of course pleurisy and pneumonia are outstanding for this. Pulmonary or coronary

infarction may cause pain in the chest, but it seems to me that a friction rub in the left chest of the type described is less likely to be due to a coronary accident than to pulmonary infarct. We are told later that the temperature was 103°, the pulse 116, and the respirations 32. I interpret those figures as being too high for ordinary pleurisy. We are also told that she did not have dullness, or change in the breath sounds, or evidence of pneumonia.

The blood pressure at the Eye and Ear Infirmary was 220/110. We are now told that after the pain had been present for two or three days the blood pressure was 140/90 and the heart sounds were very weak but regular. Of course this leads us to a point much more favorable to coronary thrombosis than to pulmonary infarct. I really do not know. I am inclined to feel on the whole that it is coronary infarct rather than pulmonary infarct.

This rub in the left chest was described as a very coarse rub. How persistent was it?

DR ALFRED L. DUNCOMBE: It was there all that evening. The following morning it was gone.

DR. SISCOE: At this point the urine showed a very large trace of albumin, a green test for sugar, and no diacetic acid. The blood sugar was 133 milligrams, the carbon dioxide combining power 52 volumes per cent. On these figures we can rule out diabetic coma and acidosis. She had a red blood cell count of 5,800,000. That may mean polycythemia, but I interpret it as being due to dehydration. The white cell count of 24,900 with 88 per cent polymorphonuclears suggests infection very strongly to me. It is unusually high for coronary thrombosis. It would be more compatible with pulmonary infarction.

This next thing I am very much interested in, the shield over the right eye. I should like to ask if there was any evidence of local infection in the operative field.

DR DUNCOMBE: We did not remove that, but the house officer from the Eye and Ear Infirmary came over and said the eye was in good condition.

DR SISCOE: I am also told a little farther back that she had an ulcer on the left great toe, the statement stops there. In a patient with diabetes an ulcer on the toe is of rather major importance. If it was simple uninfected ulcer on the toe it would not be fair to assume septicemia from a gangrenous toe.

DR DUNCOMBE: It was a very superficial ulcer that healed up.

DR SISCOE: In that case we may disregard it.

She required a large amount of sedatives. "She was mentally confused, screamed, moaned, groaned, twisted, and tried to get out of bed almost constantly." Those things suggest several possibilities, cerebral irritation for one

THE BULLETIN OF THE AMERICAN
SOCIETY FOR THE CONTROL
OF CANCER

THE letter published in another column, from the Chairman of the Massachusetts Committee for the Control of Cancer, calls attention to the *Bulletin* of this Society, and its value and interest to physicians interested in Cancer. The work of the American Society for the Control of Cancer is recognized in this country and abroad as having been one of the most effective agents in the education of the public in regard to this disease. The slow but steady improvement which has occurred in the results of treatment in the past twenty years is, in the opinion of many competent observers due in no small part to the education of the public, which has dispelled many false ideas about Cancer and has made people aware of the importance of early diagnosis and prompt and effective treatment in obtaining a cure of the disease. Much more remains to be done, of course, along these lines, not only with the public, but with the medical profession as well, and the information contained in the *Bulletin* of this Society cannot fail to be of value to every member of the medical profession.

Membership in the Society provides an opportunity to endorse the work of this important organization which should be recognized by all who may be able to contribute the required fee.

MASSACHUSETTS LEGISLATIVE
NOTES

H 755 was submitted to the Legislature on the petition of C. Ruggles Smith Secretary of the Board of Trustees of the University of Massachusetts. The Middlesex College of Medicine and Surgery is affiliated with the University of Massachusetts

Section 2 of this bill H 755 was designed to repeal that provision of the present law which permits the registration of diplomates of the National Board of Medical Examiners by the Massachusetts Board of Registration in Medicine without examination. The bill has been passed by the House of Representatives with Section 2 stricken out.

Unless other action is taken, the recognition of diplomates of the National Board remains with the Board of Registration in Medicine.

This function of state medical examination boards is operative in forty-one states of the Union.

The entire bill was killed in the Senate

NERVE-PROCESS VERSUS MIND-PROCESS

THANKS to the closely interwoven researches in neuropsychology of Sir Charles Sherrington and his coworkers at Oxford there has grown up a great body of facts in relation to nerves and their physiological functions, particularly their influence on the musculature of the body. From this point of view the brain is, also, part of "one originally uniform nerve-organ with for its main primeval office the management of those muscles, often still called the muscles of external relation." The mechanism consists of two opposing processes, excitation and inhibition, both cooperating at nodal points in the nerve circuit. As Sherrington expresses it "Their joint operation at any moment settles what will be the conduction pattern, and so the motor outcome, of the signalling going forward in the brain." Such a meagre outline naturally gives little idea

of the perfection of performance the reflex machinery can reach. We know, however, something of the strength, the speed, the direction and the steadiness of motor acts. There is also, except for the simplest reflex, a great flexibility of result. A slight difference in stimulus changes the result to one adapted to the new stimulus. Even more significant, the same stimulus can from occasion to occasion call forth different results, even amounting to actual reversal.

These and other details are carefully summarized in Professor Sherrington's Rede lecture, delivered before the University of Cambridge, England, in December 1933*. When we turn, however, from an actual nerve process to a mind-process, we reach a new field. Often the connection between the two cannot be understood for want of a common intelligible link. We may by pragmatic common sense disregard this difficulty, although we have no starting point for analysis of mental function. "The relation of mind to brain," to quote Sherrington again, "is not merely unsolved but still devoid of a basis for its very beginning. I am not a defeatist, for I would urge active pursuit of the enquiry. Even on the old line of deciphering principles of action of the brain in its management of muscle in the hope of clues to its ways of working in regard to mind. Not that any reflex principle seems applicable to mental activity. The reflex implies an end-result at which the nerve-process having shot its bolt stops and goes no further. But attempted correlation of mind with brain activity indicates for the latter through-line processes which are in no sense end-effects at all. Nevertheless, there are broad analogies. May we not think that anyhow there is no transmission from a, so to say, mental power-head, but a subtle spread of action over an unstable train, its strength at any point resting on the stability at that point. A ghost may be a very weak visual stimulus and yet release a large mental reaction."

The problem, however, is not entirely without hope, for one can hardly escape the inference that nerve inhibition must be a large factor in the working of the mind. The definite limits of exploration are not yet attained. The problem "will long offer to those who pursue it the comfort that to journey is better than to arrive, but that comfort assumes arrival." If man should arrive at an understanding of brain thinking, he "will certainly attempt to improve its ways of doing so, restraining some parts, amplifying others, introducing short cuts, and, certainly, increasing speed and aiming at economy and devising as seems to him best." Such is the aim of the neuropsychologist.

*Sherrington, Sir Charles. *The Brain and Its Mechanism*. Cambridge: The University Press. New York: The Macmillan Co., 1933. p. 35.

been assembled. There are now, as you may reckon them, three or four art shows in Boston, and as to *interest* this one ranks high

Obviously, necessarily, it includes some things that could be more expertly done technically, but even the technique is surprisingly good, often admirable.

And we have here the output of men who have worked without thought of gain, without any respect for criticism, who have *done something they wished to do* And that is the charm of the exhibition.

Dr W W Harvey's work stands out. Seven years ago, at the first doctors' art exhibit, he had vision without mastery He has learned a professional technique and shows delightful aquarelles, one at least eminently admirable

Dr J H Means and Dr Harold W Dana, competent watercolorists, are well represented.

Dr F C Irving shows a view much discussed pro and con a lake and far shore seen under pines One birch tree might be omitted from the composition, but it is good and full of right feeling

Dr J C Janney's portrait of the old derelict and the head of a girl are especially noteworthy, as well as two of his landscapes

Dr S H Sturgis has an admirable oil study of a boy's head in profile, and a "cloudscape" by Dr M A Gilbert is worth mention.

Dr F B Talbot's still lifes are amazingly good especially the African daisies, and of like meticulous and delicate workmanship are Dr J D Barney's lovely flower drawings Dr L W Baker's pencil portraits and heads by Dr E C Romberg done in his odd ingenious gold method are excellent.

In sculpture Dr W B Cannon shows two interesting heads, and Dr S C Wiggin has several pieces, and is at his best in the delightful group of three children and in the toddling boy

Dr F J Cotton has many things competent and whimsical, which interest many people. The overmantel design, Says I to He, seems to have won attention and discussion. His "Elderly Faun" is again shown

Dr H P Mosher has an admirable bit in Imhotep the first physician and quaint and interesting wood carved reliefs One wishes that he would with his ability, enlarge his scope and scale as he so well could.

Not to be overlooked is Dr L W Hill's case of 'decoys' — wonderful wood carvings of wild ducks, lovely in color and finish.

In the end the impression is of work done with pleasure in the doing of it.

This sketch does not deplete all of the very interesting products of the doctors' conception of art, and without doubt some not here mentioned may get a blue ribbon That is the trouble in trying to call attention to the work of artists but visitors may feel that adequate discrimination has not been exercised by the author of this reference

A Committee of well known artists of Boston, consisting of Charles H. Woodbury and Herman D. Murphy, painters, Joseph Coletti, sculptor, and Anthony J. Philpott, art critic, met at the Boston Medical Library on Monday afternoon, April 30, and awarded first places to the following exhibitors

Oil painting "Portrait" By James C. Janney, M.D.

Water color "Mt. Haystack, Vt." By William W. Harvey, M.D.

Pencil drawing "White Pine Blossoms" By J. Dellinger Barney, M.D.

Sculpture. "Helen." By Walter B. Cannon, M.D.

CORRESPONDENCE

THE ENLARGED BULLETIN OF THE AMERICAN SOCIETY FOR THE CONTROL OF CANCER

April 26, 1934

Editor *New England Journal of Medicine*,

The monthly *Bulletin of the American Society for the Control of Cancer* has been recently enlarged and expanded. It contains articles of interest and significance to members of the medical profession who are concerned in the treatment of cancer, as well as to those physicians who are interested in the control of the disease.

A subscription to the *Bulletin* is included in the annual membership of the Society (\$5.00), but it may also be obtained at a cost of \$1.00 a year by those who do not wish to become members. A number of physicians in other states have been glad to avail themselves of the opportunity to keep their information up-to-date on the subject. Sample copies of the *Bulletin* will be sent immediately on application to the office of the American Society for the Control of Cancer, 1250 Sixth Avenue, New York City.

Sincerely yours

CHANNING C. SIMMONS, M.D.,

Chairman, Massachusetts Committee,
American Society for the Control
of Cancer

THE RELATION OF PUBLIC HEALTH TO PRIVATE PRACTICE

To the Editor

At a recent meeting of my district society an address was given on The Relation of Public Health to Private Practice. The discussion that followed was illuminating. One physician said that he should (for the price of a visit!) be allowed to take down a measles quarantine card rather than have that service performed by a public health nurse! Does he not realize that it is because of that attitude that he is not employed more? If he were a layman would he feel that it was fair to have to pay for the visit of a supposedly skilled man to have that unskilled function performed? Small wonder that

MISCELLANY

A GROUP OF SCIENTISTS WILL VISIT THE BELGIAN CONGO

Six scientists will visit the Belgian Congo for the purpose of studying tropical diseases

The party consists of Dr Richard P Strong, the leader of the expedition, and the following named persons Dr Joseph C Bequaert, entomologist, Dr Jack H Sandground, helminthologist Hendy E Mallinckrodt, laboratory assistant and photographer Stuyvesant Pierpont, Jr, zoological assistant, and Byron L Bennett, technician

RESOLUTIONS ADOPTED UNANIMOUSLY BY THE EXECUTIVE COMMITTEE OF THE BOS TON HEALTH LEAGUE ON APRIL 26, 1934

The Executive Committee of the Boston Health League has the greatest confidence in the wisdom and ability of the members of the Survey Committee which recently made recommendations for curtailing the budget of the Health Department of the City of Boston Without having seen the tentative budget presented by the Survey Committee, and not being in possession of all the information upon which the recommendations were based, the Executive Committee of the Health League is unable to discuss the recommendations specifically Nevertheless, the Executive Committee believes

(1) That a permanent reorganization of the Health Department along modern lines as proposed by the Survey Committee should be undertaken

(2) That much money could be saved by so doing without serious impairment of service

(3) That any budgetary curtailment which may be decided upon for the Health Department should be based upon principles of effective public health administration.

(4) That a strong Advisory Council for the Health Department is essential

SUFFOLK DISTRICT MEDICAL SOCIETY

ENDORSEMENT OF THE REPORT OF THE SURVEY COMMITTEE

At a meeting of the Suffolk District Medical Society held April 25, 1934, the report of the Survey Committee appointed by his Honor the Mayor of Boston, to make recommendations relating to the Budget of the Health Department of the City of Boston, was unanimously endorsed

BLINDNESS DUE TO TRACHOMA

New York City, April 21.—'Although trachoma is the principal cause of blindness throughout the world, this eye disease is well under control in the United States and is comparatively rare in our large cities,' declared Lewis H Carris, Managing Director of the National Society for the Prevention of Blindness, just before sailing for Europe with Mrs Carris on the SS Caledonia at noon today Mr Carris and Dr Park Lewis of Buffalo, N Y,

will represent the United States at the joint meeting of the International Association for Prevention of Blindness and the International Organization Against Trachoma in Paris on May 14

'I am very happy to announce,' said Mr Carris, 'that reports from the United States Public Health Service which have just reached us indicate a downward trend in the prevalence of trachoma in this country The disease is reportable here, and for many years we have refused admission to immigrants showing symptoms of it. In the United States, trachoma is found mostly in the Ozark and Appalachian Mountain regions and among the Indian tribes of the southwest, poverty and unsanitary living conditions are important factors in its contraction and spread

'The ravages of trachoma are horribly severe in China, India, Egypt and other countries of the Orient and the Near East. Even in countries with well organized and extensive ophthalmic campaigns for the relief and cure of sufferers, it cannot be hoped that trachoma will be materially reduced until economic and general living conditions are improved and education in hygiene has developed sanitary living This disease, the greatest single world cause of vision impairment and blindness, constitutes a serious challenge to all national and international health and public welfare agencies

'The specific germ which brings on trachoma has not been definitely established, recent investigations, however, furnish clues that are expected to clear up this mystery which has baffled medical men for centuries Great progress has been made through the research of Dr P K Olitsky and the late Dr Hideyo Noguchi of the Rockefeller Institute laboratories in New York City'

Mr Carris has directed the movement for the conservation of vision in America during the last twelve years He is also the American Correspondent of the International Association for Prevention of Blindness which he and Dr Lewis assisted in forming at The Hague in 1929 Dr Lewis is Vice-President of both the American Society and the International Association for Prevention of Blindness.

PHYSICIANS' ART SOCIETY OF BOSTON

There is a very interesting exhibit of painting, sculpture, and crafts by doctors now in its second week at the Boston Medical Library

There is a queer logic about avocations Doctors as golfers do not excel as a rule, but it is no news that physicians, weary of people and of talk, turn to pursuit of the silent fish No sadism in this or satiety of talk.

And so the doctor skilled in observation, skilled in varied forms of manipulative technique learns a new technique, that of the silent hands—goes back, may one say, from the talkies to the voiceless drama

And so have a group of our colleagues done. A small, peculiar, definitely interesting exhibit has

NOTICE

MEDICAL STUDY TRIP TO HUNGARY

At the invitation of the Hungarian Medical Postgraduate Committee of Budapest, Professor Emil de Grosz President, and of the Association 'Budapest Town of Medicinal Springs' Archduke Dr Joseph Francis, President, a medical study trip to Hungary is being organized. The plans provide for a fortnight visit to Hungary during which there will be postgraduate lectures and demonstrations in English at the principal University clinics and at the municipal thermal baths and springs. Reduced railroad fares and hotel rates are granted by the Hungarian Government. The party will sail from New York on August 18 1934 visiting Munich and Oberammergau en route. The return trip may be made optionally, via Berlin Paris, or Italy arriving back in New York on September 30.

American physicians of good standing are invited to join. The American Committee of the study trip consists of Harlow Brooks M.D. Chairman Charles G. Kerley M.D. Jerome M. Lynch M.D., Wendell C. Phillips, M.D. and Erwin Torok, M.D. Richard Kovacs M.D., 110 Park Avenue, New York City, is Secretary.

REPORTS AND NOTICES OF MEETINGS

THE GREATER BOSTON MEDICAL SOCIETY

The Greater Boston Medical Society met on the evening of April 17 in the amphitheatre of the Beth Israel Hospital. Dr F. H. Lahey spoke on "The Management of Cholelithiasis and Biliary Tract Disease."

In speaking of the diagnosis of biliary colic Dr Lahey stated that the pain with its typical radiation offers little difficulty to the clinician. If the pain has subsided when the patient is first seen a very useful finding for the diagnosis is residual tenderness in the right upper quadrant. This symptom depends upon the fact that inflammation almost invariably accompanies biliary stones that give symptoms.

There are two chief types of stones found in the gallbladder. The pure cholesterol stone is the only silent stone and even this frequently gives symptoms by plugging the cystic duct and damming up the bile in the gallbladder so that it stagnates and becomes infected. The other type of stone is the calcium bilirubin calculus which is the one most frequently found in the pathological gallbladder. In this latter group of cases we quite frequently find the stones incidentally at operation or when an x-ray is made for some other purpose. But a careful investigation into the history almost invariably discloses some vague digestive discomfort or disturbance. The early diagnosis of gallbladder disease is therefore only possible by scrupulous attention to what the patient considers only minor symptoms.

In such cases the dye test has proved invaluable as a diagnostic aid. Owing to the many unfavorable

reactions to the use of intravenous dye Dr Lahey advocates the administration by mouth routinely and by the use of the intravenous method for questionable cases. The intravenous route should not be used in patients who have arteriosclerosis, or coronary disease and, in the experience of the speaker, subacute cholecystitis has probably been aggravated to the acute stage by intravenous administration of the dye.

The interpretation of the dye test should be seasoned by the clinical findings. Such conditions as acute peptic ulcer, pregnancy and spastic colitis frequently show a non-functioning gallbladder when the dye is given by any route. Then again one finds cases with typical gallstone colic that show a normally filling viscus. In such instances one should operate in spite of the dye test.

The speaker made an especial plea for early diagnosis of gallbladder disease because the mortality increases directly with the duration of the disease. Once cholelithiasis has been diagnosed whether as an incidental finding or as a possible cause of symptoms, operation should be advised. If the patient goes on to old age and develops a chronic cholecystitis he is not nearly so favorable a risk for operation. Then again he may at any time develop an acute cholecystitis in which condition he is a much poorer operative risk.

The entire question of early surgery for cholelithiasis hinges on the damage upon the biliary tree and the liver caused by the resultant infection. In this connection Dr Lahey compared gallbladder surgery with surgery on the prostate gland. Formerly the surgeon felt that his patients died from bladder sepsis when he removed the prostate gland, but now he realizes it is largely a question of kidney reserve. So in gallbladder disease the operative mortality depends upon the degree of encroachment of liver reserves by the ascending infection. To wait until the patient has had repeated attacks of biliary colic is to invite end-stage pathology with a contracted gallbladder, cholangitis and curtailed liver reserve.

In this connection Dr Lahey showed slides of x-ray films that depicted various stages of dilatation in the biliary tree. Lipiodol had been injected into the common duct postoperatively and in cases of long-standing gallbladder disease even the smallest radicals of the hepatic duct were widely dilated while the common duct was several times normal size showing the effect of back pressure upon the biliary tract.

By means of lantern slides the speaker brought out certain important points in surgical technique. Quite frequently patients find themselves suffering from the same symptoms that brought them to operation after the gallbladder has been removed. This may be the result of extensive liver damage from ascending infection but quite as often it is caused by adhesions forming between the liver bed and the duodenum owing to incomplete closure of the peritoneum over the bed of the gallbladder.

Strictures of the common duct are related largely to improper handling of the cystic artery during the

physicians are having hard sledding and that the public clinics are crowded!

Other criticisms made showed how little doctors realize how much health organizations do for us. The general feeling seemed to be that health departments, through the baby clinics, T. A. T. clinics, etc., take patients from practitioners. As a matter of fact most such clinics were started by private agencies, and were only taken over by the health departments on the request of the agencies after their value had been demonstrated. The medical profession did nothing toward this, had it, it would have been "advertising" unethically. But now that the public has been educated we doctors feel that something has been "slipped over" on us here is an apparently "good thing" and we ought to "bone in." We do not seem to realize that every child who comes to our offices for T. A. T. does so directly or indirectly because of the influence of the clinics that every child who comes for an examination and follow up, when well, does so for the same reason and that many children who would never have been known to need corrective work have been sent to us because clinics have discovered defects.

Some years ago during a rabies scare, two doctors offered to vaccinate any dog whose owner brought it to a "clinic." The only charge made was for the vaccine. The veterinarians of the town protested that their province was being invaded. A check up was made, and it was found that for every dog clinic treated, an owner went to a veterinarian and had his dog immunized privately. Had it not been for the clinic, probably none of these would have been done.

The fact that the distribution to private physicians of material from the State Laboratory is greater in those towns where public clinics are most active is a well known fact, and one on which only one possible construction can be put. Instead of combating clinics we doctors should be backing them wholeheartedly, both from selfish and altruistic motives.

Once upon a time a child went out into the world seeking happiness, but he could not find it. A fairy met him and told him to stop looking, but to give away as much happiness as he could. The first thing the child knew, he found that he had more happiness than he knew existed in all the world. We do not seem to realize that, hard hit as we are, others have been hard hit, too. Some day the depression may end. But the depression is not the real trouble, the real trouble is that we are all too selfish.

RECENT DEATHS

THE PASSING OF DR WILLIAM H. WELCH

All over the world there will be a feeling of sadness in the minds of those who know of the accom-

plishments of the great leaders in medical progress in noting the decease of Dr. William Henry Welch, April 30, 1934.

The *Journal* will make especial reference to the life of this eminent physician in next week's issue.

MACDONALD—COLIN WILLIAM MACDONALD, M.D., of 31 Hampstead Road, Jamaica Plain, Mass., died April 20, 1934.

He was born in 1858 and graduated in medicine from the Bellevue Hospital Medical College in 1887.

Dr. Macdonald practiced in Roxbury for many years. He retired from practice in 1933 and moved to Jamaica Plain. Evidence of his position in his community appears in the record of attendance of state officials and other distinguished persons at his funeral.

He joined the Massachusetts Medical Society in 1887 and was retired as of December 31, 1933. He was a member of the Council for a great many years and a past president of the Norfolk District.

Dr. Macdonald is survived by his widow, Mrs. Helen A. Macdonald, two daughters, Miss Isabel Macdonald and Mrs. John Hennessey, and one son, William C. Macdonald.

POST—ABNER POST, M.D., of 130 Brattle Street, Cambridge, died April 20, 1934. He was born in 1844, the son of Sylvester Gilbert Langdon and Sarah Marie (Post) Langdon. By request of his maternal grandfather, he changed his name to Abner Post when he was twelve years of age.

He was educated at Williston Seminary, East Hampton, Massachusetts, and graduated from Yale in 1866. Harvard University Medical School gave him his M.D. degree in 1870. He served as intern at the Massachusetts General Hospital, as assistant surgeon at the U. S. Marine Hospital at Chelsea, surgeon at the Boston City Hospital, and the Children's Hospital. He was on the staff of the Boston Dispensary for several years.

He was the oldest living Emeritus of the Harvard Medical School faculty, and a member of the honorary staffs of the Boston Dispensary, the Boston City Hospital, and the Massachusetts General Hospital. He joined the Massachusetts Medical Society in 1870, and was a Fellow of the American Medical Association, a member of the American Association of Genito-Urinary Surgeons, the American Dermatological Society, and the New England Dermatology Society. He served as Assistant Editor of the *Boston Medical and Surgical Journal* during the years 1881-1890, and was author of many monographs dealing with genito-urinary diseases.

He was a member of the St. Botolph, the University of the Yale, and the Harvard Clubs.

His wife, Laura Knight Post, died in 1927. He is survived by a daughter, Mrs. Stephen A. Breed, a granddaughter, and General Jesse F. Stevens, his stepson.

expansion, lessened capacity for work, and a striking absence of fever. There are characteristic x ray findings and persons afflicted with this disease show a distinctly increased susceptibility to tuberculosis.

Silicosis is an exclusively occupational disease. It is not contracted from the atmospheric dust on windy days, because our natural defenses are well able to protect us from the inhalations of dust occurring under ordinary circumstances. It is only when exposed to atmospheres very heavily laden with particular kinds of dusts such as occur in some industries that our natural defenses break down. For the development of silicosis, the silica inhaled must be free (not combined) and the particles must be under ten micra in greatest diameter. The number of particles per cubic foot of air must be very large. Individual susceptibility plays no part in this disease except in cases of preëxisting pulmonary disease. Dr Lanza has observed, however, that Negroes stand silicosis much more poorly than white men.

The action of silica in producing pulmonary changes is physico-chemical and as well as producing fibrosis leads to a greatly increased susceptibility of the tissues to the tubercle bacillus. The fibrotic process begins in the subpleural region and gradually progresses toward the hilum. In the absence of tuberculosis necrosis with cavity formation does not occur. Hemoptysis is seen very occasionally. The blood pressure is of no diagnostic significance. The picture is entirely different if a tuberculous process is aroused leading to the rapidly fatal outcome of "galloping consumption." There is usually a striking difference in silicosis between signs and symptoms. A patient may have distressing dyspnea using all his accessory muscles of respiration, and yet on physical examination one may find hardly more than somewhat diminished breath sounds. The presence of moist râles always means a superimposed infection.

Silicosis has long been associated with the mining industry (cf. "miners' phthisis"). The miners themselves have learned to distinguish the catching from the "not-catching" variety of consumption. The danger of silicosis in mines is entirely dependent upon whether the ore is deposited in a silica containing bed. The diagnosis of silicosis is made from a history of exposure and a characteristic x ray film. The latter shows in the early stages a generalized arborization in both lung fields with some discrete fibrotic nodulation. In the latter stages the typical snow storm appearance is produced.

From the medico-legal standpoint, the disease is classified according to various stages for purposes of determining compensation. The most recent classification is as follows:

1. Definitely negative.
2. More fibrosis than usual.
3. Decidedly more fibrosis than usual.

The above three groups are considered as negative. X ray appearances falling in the following three groups are considered positive:

4. First stage silicosis. These cases show definite discrete nodules by x ray, but are able to work.

5. Second stage silicosis. These are characterized by larger nodules and the diaphragm is frequently distorted. Their capacity for work is impaired.

6. Third stage silicosis. In these cases there is a coalescence of nodules and the patients are unable to perform any work.

Once the diagnosis is established, the prognosis is invariably poor. The majority die of tuberculosis. There is no treatment other than symptomatic for the disease, but the patients do live longer if they are kept up and about as long as possible rather than in bed. Pneumonia is a serious disease in patients with silicosis and lobar pneumonia commonly terminates in empyema.

Dr Lanza discussed other factors of importance in silicosis among them age, preëxisting pneumoconiosis and syphilis. Men over forty years of age develop silicosis twice as rapidly as younger men, and a preëxisting pneumoconiosis such as from coal dust, makes the lungs very much more susceptible to silica. Silicosis also develops about twice as rapidly in luetics. Hence it is essential that persons with strongly positive Wassermann reactions in a silicosis community receive adequate antiluetic treatment.

The prevention of silicosis is a difficult problem. The control of dust from its point of origin by means of water, exhaust ventilation, or the two combined has been of only moderate success. Once the dust is in the air, no practical means has been devised as yet to keep it from being inhaled. Dr Lanza discussed methods of dust sampling and mentioned the work being done along these lines in Dr Drinker's laboratory at the Harvard School of Public Health.

The medical supervision of employees in the silicosis trades is only palliative and an acknowledgment of the impossibility of eliminating the dust from these trades at the present time. Dr Lanza discussed the serious economic problems involved in dismissing a skilled workman from his trade because of early silicosis. The silicotic with a superimposed tuberculous infection however is a definite menace and should be pronounced disabled regardless of any other consideration.

The remainder of the lecture was devoted to the relatively more modern disease Asbestosis. This disease is due to the inhalation of a combined silicate of magnesia, zinc and nickel. The particles involved in this disease are much larger than in silicosis and they are not carried off by the lymphatics nor do they obliterate the alveoli, as occurs in silicosis. A collar of connective tissue is formed in the lung like a fine web spun criss-cross throughout the lung. Asbestos bodies were first described in 1924. They are yellowish to brown needle-like bodies often with a rounded knob at either end. Their presence in the sputum means exposure to asbestos dust and not necessarily asbestosis.

operation The artery and duct should always be ligated separately and the artery should be tied off and cut early in the operation. This latter step is important in so far as the cystic duct pursues a tortuous course compared with the artery and hence any tension on the gallbladder is referred to the cystic artery with danger of tearing it. In the event of bleeding from the artery, one should not grope blindly and attempt to snap it for fear of including the common duct in the hemostat, but by placing a finger in the foramen of Winslow exert pressure on the hepatic artery and thus control the hemorrhage while a hemostat is placed on the bleeder

In recent years the speaker has opened the common duct more frequently than before, with the result that an increasing percentage of stones has been found in the duct. A history of jaundice is not the sole criterion for opening the duct since 36 per cent of patients with proved common duct stones have had no jaundice. Any of the following findings should lead the surgeon to explore the common duct

- 1 A history of jaundice
- 2 A dilated common duct.
- 3 Palpation of a stone in the duct.
- 4 Thickening of the duct.
- 5 A contracted gallbladder

At present Dr Lahey opens the common duct in 46 per cent of cases operated upon for gallbladder disease and in 21 per cent of cases stones are found. With increase in the percentage of choledochotomy the mortality rate has declined measurably, for it removed the chief cause of blockage and resultant hepatic infection. The mortality rate for the past year was 17 per cent.

Among the postoperative patients one finds occasionally that colic persists as a symptom. In such cases duodenal drainage is of great help in determining whether a stone has been left in the common duct, for 96 per cent of the cases with cholesterol or calcium bilirubin crystals show common duct stones. When gradual, painless jaundice develops after removing the gallbladder, a stricture of the common duct should be suspected.

Courvoisier's law states that obstruction of the common duct by a stone is accompanied by a contracted gallbladder, while obstruction due to other causes gives a dilated gallbladder. Dr Lahey stated that if we add to the criterion of obstruction (1) painless, progressive jaundice and (2) persistent stools with absence of bile the law is of much greater assistance in making the differential diagnosis.

Dr Lahey spoke of the invaluable aid given by intravenous administration of glucose to the patient postoperatively. This is of benefit in sustaining the hepatic reserve and in preventing hemorrhage. In the event of postoperative hemorrhage, transfusion of whole blood should be used without stint. A brilliant example of this was a case receiving a total of eleven transfusions after operation with recovery.

The speaker advocated spinal, supplemented with local as the ideal anesthetic for gallbladder surgery. The next best is ethylene gas, then gas-oxygen, then ether, and last of all chloroform. The last two tend to produce liver damage and jeopardize an already handicapped organ.

An interesting discussion followed the paper and the meeting adjourned at 10 20.

THE WORCESTER NORTH DISTRICT MEDICAL SOCIETY

The seventy fifth annual meeting of the Worcester North District Medical Society was held at the Burbank Hospital, Fitchburg, Mass., at 1 P.M. Wednesday, April 25.

The annual oration was delivered by Dr Andrew R. MacAusland of Boston. His subject was "Recent Trends in the Treatment of Fractures." His talk was most interesting and thoroughly enjoyed by the forty five members present.

His Honor, Mayor Robert E. Greenwood, president of the board of trustees of the hospital, extended the greetings of the city to the physicians.

A committee was appointed to revise the old by laws which have been in use since 1887. A fine chicken dinner was served by the hospital. The following designated officers were elected for the ensuing year.

President C. B. Gay, Fitchburg
Vice-President C. H. Jennings, Fitchburg
Secretary F. M. McMurray, Fitchburg
Treasurer F. H. Thompson, Jr., Fitchburg
Commissioner of Trials H. R. Nye, Leominster
Councilors F. R. Dame, Athol, T. R. Donovan, Fitchburg, A. F. Lowell, Gardner, H. R. Nye, Leominster, W. F. Sawyer, Fitchburg
Censors Supervisor, T. R. Donovan, Fitchburg, J. J. Curley, Leominster, George Mossman, Gardner, F. H. Thompson, Jr., Fitchburg, A. A. Wheeler, Leominster

FRANCIS M. MCMURRAY, M.D., *Secretary*

THE CUTTER LECTURE ON PREVENTIVE MEDICINE

The Cutter Lecture on Preventive Medicine was given in the Amphitheatre of Building E at the Harvard Medical School on Friday, April 20, at 5 P.M. The speaker was Dr. Anthony J. Lanza, assistant medical director of the Metropolitan Life Insurance Company. Dr. Lanza, introduced by Dr. Milton J. Rosenau, has been a member of the United States Public Health Service and of the Rockefeller Foundation and has been interested for many years in medical problems connected with the mining industries. The subject of his lecture was "Silicosis and Asbestosis."

Silicosis was described as a disease due to breathing air containing silica (silicon dioxide) which leads to definite fibrotic changes in the lungs. The clinical picture is characterized by dyspnea, decreased chest

should be controlled not by insurance companies but by the medical profession. Insurance for hospitalized illness is well recognized in England and it has been established in 25 cities in this country, while plans are maturing in 50 other cities.

In conclusion, Dr. Smith emphasized the need for study, experiment, and the maintenance of an open mind among those who deliver medical service.

SOUTH END MEDICAL CLUB

At the regular monthly meeting of the South End Medical Club held on April 17, 1934, Dr. Richard M. Smith, Assistant Professor of Pediatrics and Child Hygiene of the Harvard Medical School, was the speaker.

His subject was "Acute Abdominal Conditions in Children." An abstract is as follows:

One of the most frequent conditions in children for which the physician is consulted is abdominal pain. In infants, serious disease within the peritoneal cavity may exist without complaint of pain. Careful judgment is necessary in both conditions to determine the exact pathological state for treatment of the various possible conditions is widely different.

In dealing with children, one must constantly bear in mind the possibility—one might almost say, so far as infants are concerned, the probability—that some congenital anomaly or retarded developmental process is responsible for the pathologic state.

Some of the common conditions giving rise to acute abdominal symptoms in infants and children will be considered from a diagnostic and medical point of view, as the general practitioner is usually the first physician called to see the ill child and upon his skill at that time may depend the life of the patient.

There was a discussion of congenital hypertrophic stenosis of the pylorus, intussusception, intestinal obstruction due to congenital abnormalities, appendicitis and its special signs and symptoms in children, abdominal symptoms associated with acute respiratory infections, diseases of the kidney producing abdominal signs, spastic colon, abdominal tumors, abdominal purpura, and allergic conditions.

With these possibilities in mind, it is important for the physician to secure in the first instance an accurate history, remembering that the facts may be colored in presentation by the point of view of the mother. Inspection should be carried out carefully before the child is disturbed and then the local examination made, recognizing the importance of slight physical signs. The rectal examination should be made last but not omitted. There should be a careful general examination, especially of the lungs for early signs of pneumonia, of the heart for evidences of general infection, of the throat and ears for signs of upper respiratory disease, and the skin for evidence of purpura and general septicemia. Certain special examinations should be made. In almost every instance, a white blood count and a urine examination and in many instances an x-ray

without barium to determine the presence of gas within the intestinal tract. In some instances, a barium examination also should be made as it is of particular interest in revealing the condition of the colon.

MASSACHUSETTS TUBERCULOSIS LEAGUE ANNUAL MEETING

The twenty-second annual meeting of the Massachusetts Tuberculosis League was held at Hotel Statler on April 12, 1934. Approximately one hundred members of the League and its twenty-eight affiliated organizations were present from all parts of the State.

The proceedings began with the annual address of the President, Dr. Frederick T. Lord, in which he pointed out the progress made by the League and its branches during the past year. He stressed the importance of cooperation with the State and County Sanatoria when they take on the work of the Chadwick Clinics. In the latter part of this year, the ten-year period for the Chadwick Clinics terminates with the end of the current school year in June. Under the plan developed for State-wide continuation of the Clinics, the State and local Sanatoria, cooperating with the local school boards, will continue the service wherever possible.

Frank Kiernan, Executive Secretary, gave an account of the work of the League, bringing out the outstanding accomplishments since April, 1933, which included a tuberculosis survey of Cambridge, an intensive study of one of the Summer Health Camps operated by an affiliated organization, and cooperation with the State and local public health authorities.

Miss Jean V. Latimer, Educational Secretary of the League, outlined the widespread and increasing use of the Tuberculosis Unit, prepared by her and published by the League last year. The Unit has been taken up in twenty states and is now being used in approximately one hundred high schools of cities and towns in Massachusetts.

At the annual luncheon meeting, the speakers were Dr. Henry D. Chadwick, State Commissioner of Public Health, and Dr. Kendall Emerson, Managing Director of the National Tuberculosis Association. The theme of their addresses was "Tuberculosis Programs in These Changing Times."

Dr. Chadwick addressed his considerations of this subject to problems in Massachusetts. He urged a closer cooperation of the volunteer tuberculosis associations and the State, County and local Sanatoria. He also recommended that the Tuberculosis Associations which operate Summer Health Camps should endeavor to secure more funds for the camp work from service organizations and constantly reduce the amount of Seal Sale money used in operating the camps. He indicated that it is the intention of the Department to endeavor to interest school physicians so that they will carry on tuberculosis testing of children as part of the school

The prominent symptoms in asbestosis are dyspnea and cyanosis. The latter is not found in silicosis. X-ray films often do not show sufficient changes to account for the symptoms. The common picture is a groundglass appearance in the lower portion of the lung fields. The shadows are softer than in silicosis and an unexplained cardiac enlargement is uniformly found.

Uncomplicated cases of asbestosis die of cardiac failure. The cases progress to a fatal termination even if removed from the faulty environment. The incidence of the disease is less among miners than in those engaged in the manufacture of asbestos. The relation to tuberculosis is unlike that of silicosis. In the examination of 300 cases of asbestosis, Dr. Lanza found little evidence of tuberculosis and he believes that tuberculosis when it occurs in asbestosis is a merely coincidental disease.

The problems of prevention and control are the same as in silicosis. In conclusion, Dr. Lanza emphasized the importance of previous occupation in the past history of any patient.

ECONOMIC ASPECTS OF MEDICAL PRACTICE

Dr. Richard M. Smith, member of the Committee on the Costs of Medical Care, presented a very interesting talk on the 'Economic Aspects of Medical Practice' on Monday, April 16, at 5 P.M. in the amphitheatre of Building C at the Harvard Medical School, under the auspices of the Phillips Brooks House Association.

In the past half century, medical men have devoted their time for the most part to the advancement of medical science with very little attention given to methods of rendering medical service. Medical service is primarily a personal matter and this relationship between doctor and patient prevailed in the rural communities of the past century. Industrialization, however, has complicated matters and various conditions of maladjustment have arisen. Among the existing difficulties, Dr. Smith mentioned the lack of coordination between the services of the specialist and the general practitioner. The latter is handicapped by being unable to judge the quality of medical care rendered. There is no available method at present for the standardization of the quality of medical service. Not only is there an inequality of service rendered, due to both natural endowment and training, but it is not equally distributed geographically. In California, for example, there is one physician per 570 population, while in South Carolina there is one per 1430. It has been estimated that to meet the demands 18 per cent of physicians should be specialists. Actual figures, however, reach 45 per cent, indicating an overabundance of specialists.

Dr. Smith discussed another group of difficulties under maladjustments in the utilization of medical facilities. This depends theoretically upon the need for medical services and the ability of people to pay for them. It was pointed out, however, that the actual demand for medical services is not the same as the

existing need for them. Even in the higher classes the demand is only 85 per cent of the need. Medical facilities are therefore not utilized, partly because the need for them is not always recognized and partly because people are unable to pay for them.

Statistics have shown that the total cost of medical care is quite unevenly distributed. About half the total cost has proved to be in connection with hospitalized illness. Dr. Smith presented a figure for the average net income of practicing physicians in 1929, which was \$5300. For salaried physicians it was \$4500. An important observation is that about 40 per cent of the physician's total income goes for overhead.

The remainder of the talk was devoted to possible solutions of the above problems. Dr. Smith pointed out that each community has to meet its own peculiar problems. He suggested the possibility of agencies, controlled by physicians, for the coordination of medical services. Careful consideration should be given to the type of medical student accepted for training as well as to the type of training offered. The development of specialists should be restricted. Fortunately there is a natural trend in this direction at the present time. The speaker favored the development of postgraduate instruction for the improvement of the quality of the service rendered by the general practitioner. Public Health activities should receive more adequate support.

The consensus at present is that most attention should be devoted to the development of the voluntary hospital. Adequate facilities for the study of patients would thus be offered in suburban districts and affiliations could be made with a metropolitan hospital for the use of more elaborate equipment or for the study of more complicated cases. The voluntary hospital would furnish a means for the supervision of the quality of medicine practiced and members of the staff would stimulate one another toward higher standards. Group Clinics are being tried at the present time but the difficulty seems to be that the personal relationship of the doctor, the patient and his family is impaired. Objections have arisen also against the control of medicine by the county medical societies.

Medical services may be paid for in three ways: (1) payment of individual fees, (2) taxation, and (3) insurance. The first is for the most part the method in vogue at the present time in this country. The second is recognized for the treatment of chronic diseases, for the army and navy, for public health and for the maintenance of local municipal hospitals. In the third or insurance method, we have to choose between voluntary and compulsory insurance. The latter can be effected only by the government and it would really lead to state medicine which may be undesirable. In countries where voluntary insurance was at first attempted the system ultimately was changed to the compulsory type. The Committee on the Costs of Medical Care believes that voluntary insurance ought to be tried but it

Tuesday, May 15, 1934, at 12 noon. The speaker will be, Hugh Barr Gray, M.D., Superintendent and Physician in-Charge, Washington Home, 41 Waltham St., Boston. His subject will be 'The Alcoholic.' All physicians are cordially invited to attend. The usual luncheon will be served.

THE HARVARD MEDICAL SCHOOL ALUMNI ASSOCIATION

The Annual Meeting of the Harvard Medical School Alumni Association will be held Saturday, May 12. Ward rounds (10 a.m. to 12 m.) and operations will be held at the Peter Bent Brigham, the Massachusetts General and the Boston City Hospitals. A business meeting and luncheon (\$1.00) will be held in the gymnasium of Vanderbilt Hall at 12:30 p.m.

PHI DELTA EPSILON FRATERNITY

On Monday evening May 7, 1934, at 8 p.m. the Phi Delta Epsilon Fraternity will hold its final Open Meeting of the year at the Evans Memorial Hospital Auditorium. The speakers and their topics for this program are Laurence B. Ellis, 'Postural Changes in Blood Pressure', Dr. Richard B. Capps, 'Vasopressor Substances in the Blood and Urine in Normal Subjects and in Patients with Arterial Hypertension'. Dr. Soma Weiss, 'The Etiology of Hypertension.'

NORFOLK DISTRICT MEDICAL SOCIETY

The Annual Meeting of this society will be held in the Crystal Room of the Hotel Kenmore May 8, 1934. Telephone Kenmore 2770.

The business meeting will be at 6 P.M., the annual dinner at 7 P.M. and following the dinner there will be an illustrated lecture entitled "The Romance of News Gathering" by Mr. Alton Hall Blackington.

Members are invited to have ladies accompany them as in the past. Tickets for members will be \$1.50 and for guests \$2.50. Reservation cards must be in the hands of the Secretary by Saturday, May 5th.

FRANK S. CRUICKSHANK, M.D., *Secretary*,
1695 Beacon St., Brookline

MIDDLESEX EAST DISTRICT MEDICAL SOCIETY

The annual meeting of the Middlesex East District Medical Society will be held at the Winchester Country Club at 1:00 p.m., Wednesday May 9.

Speakers will be Drs. C. R. Baisley of Reading, A. P. Aitken, M. J. Quinn and W. L. McKenzie of Winchester and T. E. Dinan of Wakefield.

A group picture has been arranged for

ALLAN S. CUNNINGHAM, M.D. *Secretary*

ESSEX SOUTH DISTRICT MEDICAL SOCIETY

Annual meeting Tuesday May 8, 1934 to be held at the Salem Country Club, Forrest Street, Peabody. Dinner at 7 P.M.

Speaker Dr. Paul Wakefield, Superintendent of Maine Central Sanatorium

Subject "Comparison of Public Health in China and America."

RALPH E. STONE, M.D., *Secretary*

WORCESTER DISTRICT MEDICAL SOCIETY

The Annual Meeting of the Worcester District Medical Society will be held during the afternoon and evening of Wednesday, May 9, 1934, at Worcester Country Club, Worcester, Massachusetts.

The many members will probably desire to play golf during the afternoon. The annual dinner will be served at 6:30 P.M. and this will be followed by the Business Session of the Annual Meeting at 7:45. The election of officers for the 1934-35 period will take place immediately after this business session.

The Annual Oration will be given by Dr. William F. Lynch and his subject will be "Our Early Heritage."

ERWIN C. MILLER, M.D., *Secretary*

NEW ENGLAND PEDIATRIC SOCIETY

Saturday Afternoon May 19, 1934, 2:30 D.S.T.

New Haven, Connecticut

Medical and Pediatric Amphitheatre

Room 1094, New Haven Hospital

789 Howard Avenue

2:30-2:45 — Clinical Presentation Dr. Grover F. Powers and Staff

2:45-3:00 — Mottled Enamel

Nutritional Aspects, Arthur H. Smith, Ph.D.

Clinical Aspects, Bert G. Anderson, D.D.S.

3:00-3:30 — Recent Advances in Nutrition of Interest to Pediatricians, Professor Lafayette B. Mendel.

Farnam Building, Room 2028

3:30-4:00 — Demonstration of Apparatus for Stimulating Excitable Centers by Remote Control, Richard U. Light, M.D.

Auditorium, Sterling Hall of Medicine

4:00-4:30 — The Developmental Diagnosis of Infant Behavior and Its Relation to Clinical Pediatrics. Illustrated by Motion Pictures, Arnold Gesell, M.D.

At the conclusion of this session members of the Society are welcome to visit the Clinic of Child Development.

New Haven Medical Association Building,
364 Whitney Avenue

5:00-6:00 — Social Hour

6:00 — Dinner

7:00 — Address by Dr. Louis C. Schroeder, New York City, "The American Academy of Pediatrics."

GERALD HOFFEL, M.D. *Secretary*

routine It is planned to examine the children in the seventh, ninth and eleventh grades, also to xray these children at the schools using a portable machine Interpretation of the xray pictures will be made by the sanatorium serving the school district. Dr Chadwick urged the affiliated organizations to have their nurses cooperate in helping promote these school examinations

Dr Kendall Emerson, Managing Director of the National Tuberculosis Association, discussed tuberculosis problems from the national point of view He stated that in the year 1934, there is no indication that new lines of attack on the tuberculosis problem are to be developed. He stressed the importance of intensifying the methods which have been proved to be successful here and which are gradually being adopted in other parts of the country He referred to the enormous problem of transients in the Southwest and described the attempts which the Federal Government is making to meet it. Formerly, the problem of the transients was a comparatively small one Now, with thousands of people constantly migrating from the North and East to the West and Southwest, it has become a menace to the health of the people in those sections of the country Dr Emerson emphasized the possibilities of health education open to nurses in their dealing with families and individuals in their field work He commended the League for its important contribution in the field of child health education through training teachers

The experimental work in the treatment of tuberculosis through the use of gold and BCG was described by Dr Emerson who stated that in America these methods are being constantly watched and in New York City an intensive experiment is being done with the Calmette treatment. The National Association neither approves nor disapproves of these proposed new methods but will advocate them if they are found to be successful after the experimental period

Dr Emerson concluded his address with a description of the work of the National Health Council, the Presidency of which has recently been assumed by Colonel Theodore Roosevelt.

At the election of Officers and Directors, the following were chosen for the year April, 1934 to April, 1935 President, Dr Frederick T Lord of Boston, Honorary Vice-Presidents, Dr George H Bigelow, Milton, Dr Henry D Chadwick, Boston Rt Rev William Lawrence, D.D., Boston, Rabbi Harry Levi, Brookline, and William Cardinal O Connell Brighton Vice-President, Dr Francis P Denny, Brookline, Treasurer, Mr Arthur Drinkwater, Cambridge Assistant Treasurer, Mr Romney Spring, Boston Executive Committee, Dr Walter P Bowers to succeed himself, Dr Alton S Pope to succeed himself and Mr Raymond S Patterson to succeed Mr William N Goodell, resigned, Clerk of the Corporation, Mr Frank Kiernan, Belmont. The Directors at Large are Mr Frederic Bailey, North Scituate, Dr George H. Bigelow, Milton,

Dr Walter P Bowers, Clinton, Dr Robert P Carpenter, North Adams, Dr Henry D Chadwick, Boston, Miss Josephine B Colt, Boston, Mrs Leslie B Cutler, Charles River, Dr Francis P Denny, Brookline, Mr Arthur Drinkwater, Cambridge, Dr C Benjamin Fuller, Waltham, Rev Walter F Greenman, West Newton, Mrs John D Henry, Boston, Dr William O Hewitt, Attleboro, Professor Murray P Horwood, Newton Centre, Dr Roger L Lee, Boston, Dr Frederick T Lord, Boston, Dr Carl C MacCorison, North Wilmington, Dr Richard P MacKnight, New Bedford, Mr David Moxon, Framingham, Mr Raymond S Patterson, Newton, Dr Alton S Pope, Newtonville, Dr Sumner H Remick, Waltham, Mr John Ritchie, Maiden, Mr Thornton K Ware, Fitchburg, Miss Margaret Welr, Beverly

The Representative Directors are Mr George E Dean, Falmouth, Dr Floyd R Smith, Pittsfield, Dr John B Hawes, 2nd, Boston Dr Donald S King Boston, Mr Alexander Wheeler, Boston, Miss Sarah Hyams, Jamaica Plain, Dr Garnet P Smith, Attleboro, Mrs Mabel Greeley Smith, Cambridge, Mrs E Frank Guild, Chelsea, Dr Olin S Pettingill, Middleton, Mrs H G Hamann, Swampscott, Mrs A. L Johnson, Orange, Mr Walter S Barr, West Springfield, Mr Clifton H. Hobson, Palmer, Hon. Clarence E Hodgkins, Northampton, Dr Frederick R Radcliffe, Haverhill, Dr S L Skvirsky, Holyoke, Mrs Frances B Mowry, Salem, New Hampshire, Mr Charles H. Hobson, Lowell, Mrs Carolyn M. Engler, Lynn, Dr Samuel Hoberman, Malden, Mr Richard C Maloney, Nantucket, Dr James F Brewster, New Bedford, Mrs Allan Shepard, Newburyport, Mrs Charles Riley, Chestnut Hill, Dr Nahum R Pillsbury, South Braintree, Mrs William C Rogers, Cohasset, Mrs Ralph S Drury, North Leominster, Mrs B Milo Burke, Brockton, Dr J Frank Donaldson, Salem, Mrs Albert Cross, Weston, Mrs T F Kimball, Belmont Rev J F McGillicuddy, North Brookfield, Mrs Chandler Bullock, Worcester, Dr Arthur K Stone, Framingham Center

WILLIAM HARVEY SOCIETY

The next meeting of the William Harvey Society will be held Friday, May 11 in the Auditorium of the Beth Israel Hospital, Boston, at 8 P.M.

PROGRAM

Speaker Dr Archibald Malloch, Librarian, New York Academy of Medicine

Subject "William Harvey"

Chairman Dr Charles F Painter, formerly Dean, and Professor of History of Medicine, Tufts College Medical School.

SOUTH END MEDICAL CLUB

The next regular meeting of the South End Medical Club will be held at the office of the Boston Tuberculosis Association, 554 Columbus Ave, Boston, on

The New England Journal of Medicine

MAY 10, 1934

NUMBER 19

NEW ENGLAND SURGICAL SOCIETY

A STUDY OF TWO HUNDRED AND THIRTY-SIX COMPOUND FRACTURES TREATED AT THE MASSACHUSETTS GENERAL HOSPITAL*

BY ERNEST M. DALAND, M.D.†

DURING the period 1923 to 1931, two hundred and thirty-six compound fractures were treated in the wards of the Massachusetts General Hospital besides compound fractures of the skull, face and jaw, which are excluded from this report. Two hundred and fourteen were fresh fractures and twenty-two were old cases. The end results are known in one hundred and fifty-one fresh cases and eighteen old cases.

The treatment of compound fractures involves the double problem of dealing with the fractured bone and the injury to the soft parts. The purpose of this study is to determine from our own experience what is the most satisfactory method of handling lesions of this type.

The damage to the soft parts varies according to the mechanism of the fracture and according to the degree of trauma. The damage is not so great when the fracture is due to indirect trauma, in which case the bone ends are forced out through the skin, as it is when an external force injures the soft tissues before breaking the bones. We have classified these compound fractures as follows:

- 1 Indirect violence
 - a Puncture wounds
 - b Extensive soft tissue damage occurring from within out
- 2 Direct violence
 - a Cuts, lacerations and bullet wounds
 - b Extensive wounds from massive trauma

By "sepsis" in this report, we mean the development of a purulent discharge in the wound. Minor stitch abscesses have been included as septic wounds even though they were not serious enough to change the result.

TREATMENT

On entry to the hospital, morphine is given in sufficient quantities to relieve pain. The wound is carefully inspected to determine the amount

of soft tissue damage. Injuries to blood vessels, nerves, muscles and tendons are noted, and a decision is made as to what structures can be saved and what must be sacrificed. The skin around the wound is cleaned with benzine and is shaved, the operator shaving away from the wound with a sterile razor. Ether is used to dry the skin. Iodine is then applied to the skin and the wound covered with a sterile dressing. In some instances no further attention may be paid to the compound wound, but later we shall learn whether such treatment is safe. The patient is then ready for a more careful palpation of the fractured bones and for an x-ray examination. Temporary splints must be applied before the patient is transported to the x-ray department.

Antitetanic serum is given to all patients with compound fractures. A preliminary test is made to determine possible sensitivity to horse serum by injecting 0.1 cc. of the antitetanic serum intradermally. If there is no skin reaction in twenty minutes, an intramuscular injection of 1500 units is given, if the patient is an adult. A child receives a lesser dose, according to his age. If the patient is sensitive to horse serum, he is desensitized by giving small amounts subcutaneously at half-hour intervals. The doses are gradually increased until the full amount is given. Adrenalin is used to combat any untoward reaction.

If the wound is more extensive the same preliminary treatment is carried out. x-rays taken and the patient sent directly to the operating room. In the meantime a visiting surgeon has been called and he usually carries out the operative treatment. If shock is present, the patient is kept on the "shock table" until transportation is thought safe. Occasionally operation is done with him still on the "shock table." Ether or gas oxygen is the anesthesia of choice.

The operative procedure consists of a thorough debridement. The wound must be opened up widely and the bone ends exposed. Four to ten quarts of normal salt solution are used to irrigate all parts of the wound thoroughly, the assistant opening up various parts of the wound. This is a very important feature of the treat-

*From the Fracture Service of the Massachusetts General Hospital.

Read at the Annual Meeting of the New England Surgical Society September 30, 1933 at Boston.

MASSACHUSETTS GENERAL HOSPITAL

A Clinical Meeting of the Staff of the Massachusetts General Hospital will be held in the Moseley Memorial Building, on Thursday, May 10, 1934, at 8 15 P M

PROGRAM

1 Certain Aspects of Lung Abscess Based on a Study of Two Hundred and Ten Cases—Dr Frederick T Lord and Dr Donald S King

2 Benign Tumors of the Bronchus—Dr Donald S King

3 Lobectomy and Total Pneumonectomy — Dr Edward D Churchill

Physicians, medical students, nurses and social workers are cordially invited.

COMMITTEE ON HOSPITAL MEETINGS

ESSEX NORTH DISTRICT MEDICAL SOCIETY

The Ninety Third Annual Meeting of the Essex North District Medical Society will be held at the Andover Country Club on Wednesday, May 9, at 12 30 P M, at which time there will be a dinner followed by the business meeting At 2 00, Dr L M Hurxthal will give a motion picture demonstration of synchronized heart action, and electrocardiograms At 2 30, Dr L E Phaneuf will address the meeting on "Office Gynecological Methods" At 3 00, Dr John Sproull will speak on "A General Practitioner Looks at Coronary Thrombosis and Angina Pectoris"

There will be an opportunity for the members to play golf

E S BAGWELL, M D, *Secretary*

HARVARD MEDICAL SOCIETY

The next meeting of the Harvard Medical Society will be held in the Peter Bent Brigham Hospital Amphitheatre (Van Dyke Street entrance), Tuesday evening, May 8, at 8 15 P M

PROGRAM

Presentation of Cases

Factors Controlling the Peripheral Blood Flow in Man By Dr Norman E Freeman

Studies on the Innervation of the Blood Vessels and Their Application to Neurovascular Surgery By Dr James C White

Dr Walter B Cannon will preside

JOHN HOMANS, M D, *Secretary*

TRUDEAU SOCIETY

The next meeting of the Trudeau Society will be held at the Worcester County Sanatorium, West Boylston Mass, on May 8 at 4 P M Dr Richard H Overholt of the Lahey Clinic will speak on Thoracoplasty

the majority of patients applied for treatment immediately after the injury, forty-nine in twenty-four hours, and five others two, three and seven days after injury. Two were classified as old cases, these were seen two weeks and four months respectively after injury.

tment

	Sepsis	
Dressing with or without antiseptic	7	1
Amputation—left open	1	0
Amputation—closure	12	1
Debridement	14	0
Débridement—closure	14	0
Débridement plus Carrel-Dakin treatment	5	1
Débridement plus amputation plus Carrel-Dakin	1	1
	54	4

Some of these cases are really traumatic amputations but frequently an attempt was made to save certain fractured phalanges with the aid of others hence the impracticability of classifying these into two groups. It will be noted that there were four septic cases in spite of the treatment given. In two cases without results we do not know about the sepsis so that there are four septic cases out of fifty-two approximately eight per cent. It is of interest to note that there were no cases of tendon sheath infection. Apparently the infection does not travel up a tendon sheath already opened up at its distal end. There were no cases of result; osteitis. Amputation of one or more phalanges was done primarily fourteen times and secondarily twice. There were no cases of gas gangrene infection or tetanus and no deaths. The average time in the hospital was two weeks. There were but four patients in this group who did not resume their former work. The amount of disability depended on the extent of the amputation required. The disability in the septic cases was no greater than in those which remained clean.

BONES OF FOREARM (43 cases)

There were forty-three cases in this series with final results in twenty-eight. All were re-

cent cases, thirty-six were treated within twenty-four hours of injury. Two delayed twenty-four hours, one, two days, two three days, one, four days, and one five days.

It was impossible to determine from the records which cases had small puncture wounds from indirect trauma and which had larger wounds produced from within out, so all of the indirect trauma cases have been classified as puncture wounds. There are twenty-five cases of puncture wounds, five cases of cuts and lacerations.

Many of the groups contain too few cases to make any deductions as to the value of the treatment. However, it is to be noted that of the sixteen cases treated by cleansing the wound and leaving it open fifteen stayed clean. These were the small puncture wounds made by splinters of bone with very little soft tissue damage. There was potential but not much actual soiling of the wound. The wound was not sutured in any of these cases. Sepsis occurred in six per cent of the cases.

The next group was made up of larger, dirtier wounds in which a debridement was done. The operator found little soft tissue damage and thought it safe to close the wound. Sepsis occurred in twenty-nine per cent of these cases.

The next group was debrided and left open with sepsis appearing in one case in four (25%). The final group was debrided and subjected to Carrel-Dakin treatment with sepsis in two out of six cases (33%). The last two groups were obviously the most severe cases.

In eight cases we find that traction was used to accomplish or maintain reduction. The majority of arms were mobilized by plaster casts, or by anterior and posterior splints of wood or plaster. Bone plates were used at secondary operation in five instances but never in a primary operation. One other secondary open operation was done. Carrel-Dakin tubes were inserted at the primary operation in eight of the cases. The tubes were left in for periods of from four days to four weeks. In but one case

ment Unless the wound is well opened up, the infected material will be forced into the wound instead of being washed out. The skin edges are excised and all traumatized and infected tissues are removed. Several knives are used in succession, as a sharp knife causes less trauma than a pair of scissors. All traumatized fat, fascia and muscle must be cut away. Normal

of compound fractures and we have rarely used steel plates. Skeletal traction may be applied distal to the wound, provided this procedure is carried out as a clean operation.

The problem of whether to close the wound and whether to use the Carrel-Dakin method now must be considered. Certain of the smaller compound wounds may be closed without drainage.

muscle may be recognized by bleeding and twitching when it is incised. Small bone fragments unattached to periosteum should be removed and the edges of soiled bone trimmed with rongeurs. Large fragments with periosteum attached to them should be thoroughly cleaned and put back. Even if they do not live, their calcium content may aid in establishing union.

A reduction of the fracture may be accomplished at this time unless it is necessary to open up new areas. We do not advocate the use of bone grafts or bone pegs in the primary fixation

If Dakin solution is to be used, the tubes must be inserted at the time of operation and the instillation of the solution started at once. Details of the Carrel-Dakin treatment are considered at the end of this paper.

PHALANGES AND METACARPALS (56 CASES)

There were fifty-four fresh compound wounds and two old wounds. All were due to external violence, usually associated with industrial occupations. Crushing between two objects or in machines, injuries in cutting machines or being struck by heavy weights were common causes

PHALANGES AND METATARSALS (16 CASES)

There were sixteen cases, eleven with final results and five without. All patients applied for immediate treatment but one, who delayed two days. The usual cause was the falling of a heavy weight (eleven cases), one was a crushing injury and in two the causal agent was a bullet or gun-shot charge.

TARSUS (8 CASES)

There were five fresh and three old compound fractures or dislocations of the tarsus in our series. Of the fresh cases, one was due to a bullet wound, two to falls, one to a railroad accident and the other was caused by a heavy weight falling on the foot.

There were no cases of tetanus or gas bacillus.

TABLE V
COMPOUND FRACTURES OF THE HUMERUS

Method of Treatment	Indirect Violence		Direct Violence		Totals
	Sepsis	No Sepsis	Sepsis	No Sepsis	
Wound cleansed with closed reduction	1			1	2
Débridement and closure		1		2	3
Débridement, wound left open				2	2
Débridement and Carrel Dakin		1	1		2
Amputation for gas bacillus infection	1				1
Totals	2	2	1	5	10

Carrel-Dakin treatment was used in two cases and in both the wounds remained clean. There were no gas bacillus or tetanus cases, no deaths and no resulting bone infection. The average hospital stay was three and one-half weeks, the longest was eleven weeks and the shortest, one week. Four patients required secondary amputations of one or more phalanges.

The immediate results are shown in table VI. The final results are known in eleven cases. Two were given a perfect rating. Five others had excellent results considering that one or more phalanges had been removed. Two patients were able to do their work and had a good functional result after the amputation of one toe. There were two poor results, one a traumatic amputation of two toes and the other due to a crushing injury of the first metatarsal and proximal phalanx.

infection and no deaths. The average hospital stay was seven weeks. The Carrel-Dakin treatment was not used in any case as a primary measure.

Treatment was as follows

Débridement and closure	1—no sepsis
Débridement and astragalectomy	2—no sepsis
Débridement and reduction	2—both septic— with secondary amputations

The final results were known in only two cases. One patient had an astragalectomy with fair function and he was able to do about three-fourths of his usual work. Another with a compound dislocation of the astragalus had about half his usual function and had to change his occupation.

TABLE VI
TREATMENT OF PHALANGES AND METATARSALS

	Cases	Sepsis	No Sepsis
Antiseptic dressings	1		1

Amputation toe with closure	2		2
No treatment	1	1	
Totals	16	3	13

Summary Wounds closed 7—sepsis 1
 Wounds left open 3—sepsis 1

The problem of the treatment of compound fractures of these bones is much the same as in the bones of the hand. The degree of the original injury determines the final result to a certain extent. Amputations are frequently necessary to give the best result.

BONES OF LEG (72 CASES)

There were sixty-four recent compound fractures of one or both bones of the leg and eight old cases. End results were obtained in fifty-one of the fresh cases. Fractures extending into the knee joint and fractures of the ankle,—few

was the degree of infection watched by the use of bacterial smears. In that case smears were made every day until they were negative for organisms.

There were no cases of persistent bone infection, no gas bacillus or tetanus infections and no amputations. There were two deaths, one from fracture of the pelvis occurring two hours after admission and one from sepsis. The latter patient also had a compound fracture of the humerus, and both compound wounds remained infected until his death in nine days. He had been admitted twenty-four hours after being caught in a windlass. Débridement was done and Carrel-Dakin treatment was given. The mortality in the series was two and four-tenths per cent.

The duration of the hospital treatment in forty cases (excluding a case with a fractured femur and the patient dying of a fracture of the pelvis) averaged three and one-half weeks. The longest time was thirteen weeks and the shortest time, three days.

A study of the cases shows three poor results. One patient who developed sepsis had a poor anatomical result, fair function and was able to resume his work after a year. A second, who

tial closure with drainage, it should either be tightly closed or left open.

HUMERUS (15 CASES)

There were fifteen cases in this series. Of these, ten cases were due to recent injuries and five cases were from old injuries. End results were determined in eight new and three old cases. Of the ten fresh cases, eight were seen in the first twenty-four hours, one a day after injury and one four days after injury. Two were puncture wounds, two were more extensive wounds from within out, one was due to a cut, and five were due to massive direct trauma.

There was one case of gas bacillus infection in a four-day-old wound and immediate amputation was done with recovery. There was one death from sepsis in a day old compound fracture of the humerus associated with a similar wound of the forearm. There were no persistent bone infections. Table V shows the immediate results by the various methods of treatment.

The end result study showed practically a perfect result in twelve out of twenty-eight cases. Besides the death mentioned above there

TABLE IV
SUMMARY OF TREATMENT OF BONES OF FOREARM

	Sepsis	No Sepsis	Total	% Sepsis
Wound cleansed.....	1	15	16	6
Débridement	5	13	18	27
Débridement and Carrel Dakin.....	2	4	6	33
Wound closed.....	4	10	14	29
Wound left open.....	4	22	26	15

also had compound fractures of his fingers, developed sepsis and finally had very poor function of the arm and was unable to do much work. A third, who was a watchmaker, developed so much stiffness in his fingers that he could not return to full duty at his trade.

Twelve patients out of twenty-eight in whom the final results are known had practically perfect results. In eight cases there was either some deformity, some limitation of function, or change in the economic status, but the results were considered to be fair.

Comment

Our experience has been that simple cleansing of a small puncture wound in the arm with the application of iodine to the skin is a safe procedure if there is no gross contamination. The wound should be left wide open and we believe the Carrel-Dakin treatment offers additional protection. Our cases that have had a débridement and closure have shown a much higher percentage of sepsis than those left open. We do not advocate loose closure of the wound or par-

was one death in an untreated case. Eleven cases showed some deformity, five of these had some slight impairment of function but all resumed their former occupations. There were three poor results. The first was in a septic case where there was a full year of disability. He had a poor anatomical result, fair function and was able to do his usual work. The second was in a case with compound fractures of the fingers, wrist and sepsis. He was unable to resume work. The third was in the watchmaker mentioned above who also had compound fractures of the bones of the forearm.

We believe that in compound fractures of the humerus, careful débridement should be done in all cases. Sepsis may mean non-union and must be avoided.

SCAPULA (2 CASES)

There were two minor fractures of the scapula. The compound wounds healed without sepsis after the application of antiseptics. The end result was known in but one case, this patient had a good functional result.

al traction was used in twenty-nine. Steinmann pin being inserted through alais. Delayed union was noted in one h skin traction and non-union in three which skeletal traction was used. Non-occurred, therefore, in ten per cent of the uses with skeletal traction. Bone grafts none in the three cases of non-union with sults.

idary amputation was done five times. 1 attempt had been made to save the limb eat the fracture. Three of these were sis, one for poor circulation, and one for ary hemorrhage in the presence of sepsis.

e degree of sepsis was noted in thirteen as follows:

ase 1 Traumatic amputation one leg frac-
b leg and femur on other side. Ampu-
ot second leg for sepsis. Death.

ase 2 Débridement with loose closure. Skel-
traction. Minor sepsis.

ase 3 Multiple fractures—b b leg, ulna,
le, pelvis. Wounds cleaned. Died of sep-
id pneumonia.

ase 4 Tibia protruding, débridement. Car-
rak treatment, skeletal traction, mild sep-
nd later sequestrectomy.

ase 5 Large, direct trauma wound debrided
left open, skeletal traction, sepsis, second-
hemorrhage and amputation.

ase 6 Fracture from within out, debride-
t, Carrel-Dakin treatment, sepsis, seques-
tomy.

ase 7 Puncture wound, hit by fire truck.
nsed and dressed, closed, amputation in ten
s for sepsis.

ase 8 Débridement, Carrel-Dakin treat-
it, skeletal traction. Amputation for sepsis
two weeks.

ase 9 Débridement, closure sepsis and se-
strectomy.

ase 10 Débridement, skeletal traction sep-

ase 11 Extensive soft tissue maceration,
assing only, extensive sepsis and later exten-
e débridement.

ase 12 Débridement, skeletal traction, sep-
; bone infection, sinus.

ase 13 Débridement with loose closure,
st, slight skin sepsis.

eaths

There were four deaths, as follows (mor-
ality 6.3 per cent):

1 Traumatic amputation one leg, secondary
mputation other leg for fractures and sepsis.

2 Multiple fractures. Sepsis and pneumonia.

3 Fractured skull (four days).

4 Uremia following multiple fractures
(twelve days).

The average hospital stay (excluding the

deaths) was ten weeks. The shortest time was
two and a half weeks and the longest (includ-
ing three admissions) was twenty-eight weeks.

Results

1 Puncture Wounds (20 cases)

11 cases—practically perfect in every
way.

5 cases—economically the result was
perfect. Slight deformity and
slight disability.

1 case—slight deformity, slight dis-
ability functionally, slightly lim-
ited at old job.

1 case—amputation for sepsis.

1 case—death from sepsis and pneu-
monia.

1 case—death from other causes after
discharge.

2 Extensive fractures from within out (12 cases)

5 cases—practically perfect.

2 cases—slight deformity but other-
wise good.

1 case—delayed union. Function only
fair.

1 case—sepsis. Some deformity and
function fair.

1 case—delayed union. Considerable
deformity.

1 case—death from uremia.

1 case—death from other causes after
discharge.

3 Lacerations (3 cases)

2 cases—practically perfect.

1 case—slight deformity and slight
limitation of function.

4 Massive Direct Trauma (17 cases)

9 cases—practically perfect.

1 case—satisfactory except for slight
deformity by x ray.

2 cases—fair function slight deformi-
ty unable to do former work.

3 cases—amputations.

1 case—death from fractured skull.

1 case—death from traumatic ampu-
tation of one leg secondary ampu-
tation of other leg.

Comment

As in the fractures of the bones of the arm, our results show that the mild puncture wounds are satisfactorily treated by cleaning the wound and leaving it open after sterilizing the skin (10 per cent sepsis). It has not been our custom to close these wounds, although it was done successfully in one case.

If the wounds are larger débridement and exploration of the wound are indicated. We have closed some of these wounds which did not appear dirty and we advocate closure in selected cases. Our results showed thirty-three per cent sepsis when closure was done and nineteen per cent when left open.

In the larger wounds and those caused by direct trauma we advocate débridement and the instillation of Dakin solution according to the Carrel-Dakin technique.

Our results show too many septic cases in the

in each group—have been grouped with the fractures of the shafts in this study. This group of compound fractures is the largest and perhaps the most important of any in our series.

All but one patient applied for treatment immediately after injury. Automobiles were the cause of injury in forty-two out of sixty-four cases. It is to be noted from the following table that patients with auto injuries fall into all four groups.

Cause of Fractures

1 Puncture wound (24 cases)	
Struck by auto	15
Auto accident	2
Fall	4
Crush between trucks	1
Struck by train	1
Collision of baseball players	1
2 Extensive fractures from within out (14 cases)	
Caught foot	2
Struck by auto	6
Fall	5
Heavy weight falling	1
3 Lacerations (4 cases)	
Run over	1
Auto accident	1
Struck by auto	1
Crush	1
4 Massive direct trauma (22 cases)	
Fall	1
Caught between railroad cars	2
Crush by heavy weight	4
Run over	3
Struck by auto	7
Auto accident	5

Table VII shows the various methods of treatment with various combinations of (1) cleansing or debridement of the wound, (2) closure or not, (3) skeletal traction and (4) Carrel-Dakin treatment. The groups are too small to be of statistical value. Of twenty cases treated by simple cleansing of the wound or by the application of iodine there were but two cases of infection, but these were the mildest compound cases. Débridement with closure showed four septic cases out of twelve. Débridement with or without Carrel-Dakin treatment was done in forty-four cases with ten cases of sepsis.

However, when we consider the table from the type of fracture we find that nearly all the septic cases came in the group of massive direct violence and that these cases showed forty-seven per cent septic cases. This is a very unsatisfactory result. However, it is to be borne in mind that before the development of the debridement technique many of these limbs would have been considered beyond aid, and amputation would have been considered. The percentage of sepsis in this entire group was eighteen.

Carrel-Dakin treatment was used in twenty cases. There was one case of tetanus in an old case admitted twelve days after injury. This case is discussed later. There were no gas bacillus cases. Three patients developed bone sepsis with later removal of sequestra. One patient had a persistent sinus one year after injury.

Sepsis

In table X we present a summary of the septic cases. In some of these the amount of sepsis was very mild and did not in any way complicate the result.

Sepsis According to Method of Treatment

Table XI shows the relative sepsis in the cases treated by antiseptic dressings, and débridement with closure. Those cases treated by the simplest methods, because they were the mildest cases, gave the lowest percentage of sepsis (14). The wounds that were débrided and closed were the ones that the operator thought would stay clean without drainage. They gave sixteen per cent septic results, while the cases débrided and left open showed twenty per cent septic cases.

Bone Plates

It has not been our practice to use any foreign material for the fixation of fractures which have been compounded, although many of us

believe it is a safe procedure in certain cases, provided the wound is left open and Dakinized. One case in this series was so treated. Healing occurred without sepsis.

Mortality

There were eight deaths in this series. One patient was untreated and died immediately. One died of a simple fracture of the skull, leaving six deaths as a result of compound fractures which were treated. The mortality was two and nine-tenths per cent.

Tetanus Infection

All cases in this series were given antitetanic serum. As previously stated, one patient developed tetanus on the twenty-fourth day after admission for a gunshot wound of the thigh, femur and knee joint. Because of the initial injection the disease ran a mild course and the patient recovered after receiving 180,000 units of antitetanic serum.

Another patient was admitted twelve days

extensive wounds from direct violence, the most complicated of the compound fractures

PATELLA (3 CASES)

There were three cases of compound fracture of the patella, two fresh and one old. The first was subjected to débridement and healed without sepsis with a perfect result. The second wound was debrided and the fragments sutured with kangaroo tendon. There was no sepsis but the final result is unknown.

FEMUR (17 CASES)

Fourteen fresh cases and three old cases comprise this series, a total of seventeen. End results were obtained in eleven new and one old case. One patient was admitted three days after treatment, but the others applied for treatment at once.

The cause of injury was fall, eight cases, bullet wound, two cases, automobile or truck accident, four cases. Table VIII indicates the methods of treatment and the immediate result.

There were two cases of bone infection requiring sequestrectomies. There was one case of tetanus with recovery, no cases of gas bacillus infection and one death (mortality 7 per cent). This death was due to sepsis and occurred on the fourth day. One secondary amputation was done for diabetic gangrene of the injured leg.

Case 5 Sepsis after open operation. Amputation for diabetic gangrene.

Results

There were two of the eleven cases seen at the end of one year in whom the result was practically perfect. There was one death. All of the others were rated as having but fair function, anatomical result or economic efficiency, being deficient in one or more of these groups. All patients were able to continue their old occupations.

Comment

Compound fractures of the femur are so serious that we feel that radical treatment is the safest. In our series of five cases treated by cleansing and applying antiseptics we were lucky enough to have three wounds stay clean. We believe that these wounds should all have been treated by débridement and all left open. All wounds of any size should receive Carrel Dakin treatment as well.

PELVIS (3 CASES)

There were three cases in this group. The first case showed a puncture wound of the ilium, associated with a dislocation of the shoulder. The wound was treated with an antiseptic dressing with no sepsis and with an excellent result.

TABLE VIII
COMPOUND FRACTURES FEMUR

Débridement and Carrel Dakin and Skeletal Traction				1			2	1	4
Totals	2	5	0	1	0	1	3	2	14

Excluding the patient who died, the patients spent four months on an average in the hospital. The longest time was eight months and the shortest three and one-half weeks.

Sepsis occurred in five cases (45 per cent). The cases are cited briefly.

Case 1 Puncture wound, treated elsewhere for three days. Dressing only at Massachusetts General Hospital. Sepsis.

Case 2 Fire engine crash, death in four days from sepsis.

Case 3 Bullet wound, sepsis.

Case 4 Gunshot wound, phlebitis, sepsis, tetanus. Recovery.

The second case was one of massive external violence, associated with a compound fracture of both bones of the leg. The wound was débrided and there was no sepsis. The patient died of uremia, not associated with the fracture.

The third patient had a puncture wound which was treated with an antiseptic dressing without sepsis or complications.

GENERAL CONSIDERATIONS

Anesthesia

The type of anesthetic used is summarized in table IX. Ether seemed to be the favorite.

*Number of septic cases shown in brackets.

Sepsis

In table X we present a summary of the septic cases. In some of these the amount of sepsis was very mild and did not in any way complicate the result.

Sepsis According to Method of Treatment

Table XI shows the relative sepsis in the cases treated by antiseptic dressings, and débridement with closure. Those cases treated by the simplest methods, because they were the mildest cases, gave the lowest percentage of sepsis (14). The wounds that were débrided and closed were the ones that the operator thought would stay clean without drainage. They gave sixteen per cent septic results, while the cases débrided and left open showed twenty per cent septic cases.

Bone Plates

It has not been our practice to use any foreign material for the fixation of fractures which have been compounded, although many of us

believe it is a safe procedure in certain cases, provided the wound is left open and Dakinized. One case in this series was so treated. Healing occurred without sepsis.

Mortality

There were eight deaths in this series. One patient was untreated and died immediately. One died of a simple fracture of the skull, leaving six deaths as a result of compound fractures which were treated. The mortality was two and nine-tenths per cent.

Tetanus Infection

All cases in this series were given antitetanic serum. As previously stated, one patient developed tetanus on the twenty-fourth day after admission for a gunshot wound of the thigh, femur and knee joint. Because of the initial injection the disease ran a mild course and the patient recovered after receiving 180,000 units of antitetanic serum.

Another patient was admitted twelve days

after receiving a compound fracture of both bones of the leg. Tetanus infection was present on admission. The leg was amputated but the patient died in five days.

The incidence of tetanus in this series of two hundred and seven patients with two hundred and thirteen compound fractures was forty-eight one hundredths per cent.

Osteitis

There were five cases of persistent bone infection which was an osteitis rather than an osteomyelitis. Sequestrectomy was done in each

reserved for the most extensive injuries. For this reason it is unfair to determine the results of the treatment by the percentage of septic cases. The percentage of sepsis is higher than in the cases not so treated.

The technique of the treatment was not carried out accurately in many of these cases. In some instances Carrel-Dakin tubes were inserted in the wound at the time of operation, but the instillation of Dakin solution was not started until sepsis appeared. In other instances the tubes were not introduced into the wound until it became septic. In but one case was the degree

TABLE XI
SUMMARY OF TREATMENT AND SEPSIS

instance with immediate healing. Three of these were in fractures of both bones of the leg and two in femurs. One other patient in the first group had a persisting sinus at the end of one year. The incidence of osteitis in the entire series was two and nine-tenths per cent.

Gas Bacillus Infection

No case which received primary treatment for the compound wound developed gas bacillus infection. Gas bacillus prophylactic serum was not used at all in this series.

One boy of ten was admitted with gas bacillus infection four days after injury was incurred by falling from a piazza. No primary débridement was done. The fracture was reduced and put up at a right angle. In spite of an immediate rise in temperature, the apparatus was not removed for four days at which time gas infection was found. On admission to the Massachusetts General Hospital, disarticulation at the shoulder was done and the boy recovered.

There were other gas bacillus infections in the hospital during the period of this report, but they occurred in traumatic amputation cases, where no attempt was made to deal with the fracture.

Carrel-Dakin Treatment

A study of the cases treated by the Carrel-Dakin treatment shows that this treatment was

of infection checked by careful examination of bacterial smears. For this reason the treatment was frequently discontinued before the infection had cleared up. Numerous cultures were made, but these showed what organism was present and not how many organisms.

Table XII shows the results of the Carrel-Dakin treatment by groups. The largest group in which it was used was in the bones of the leg and the femur. The results were most satisfactory in the bones of the leg. Obviously, the fact that the percentage of sepsis in the Carrel-Dakin cases was higher than in those not so treated is not an argument against its use in the severe cases. Actually, many limbs were saved by its use.

The Technique of Carrel-Dakin Treatment

In this hospital we have always used Dakin solution, made up by the direct chlorination method described by Dakin. This method is practical only in a large hospital. In smaller hospitals and in a general surgical practice, we have found hypochlorite (made by the Bethlehem Laboratories) quite as satisfactory. Indeed, Sherman of Pittsburgh has always used this and he is one of the strongest advocates of the Carrel-Dakin régime.

Dakin solution and hypochlorite have properties which kill bacteria in a wound without injuring

the tissues. The primary purpose in using it then is to *sterilize* wounds. Irrigation of the discharges from the wounds is also an essential feature. The solution *dissolves pus* and sloughs, changes them to chloramines which are irrigated from the wounds and on to the dressings. It has the power of *stimulating* healing and by its correct use septic wounds can be quickly changed to clean wounds, ideal for secondary suture.

Technique (as described by Carrel)

1 Small rubber tubing made of a special chlorine-resisting rubber is prepared in one foot lengths with a silk ligature about one end and

and not till then, the irrigations may be stopped. One organism will give a positive culture, hence cultures are useful only in determining the organism and not the degree of sterility.

5 Small squares of finely woven compress cloth or linen are now laid over the tubes to keep them in place, but they or gauze sponges must never be packed in the wound. Failure to observe this point will result in failure of the Dakin treatment.

6 Fluffed gauze is placed about the wound to absorb the discharges. One pad large enough to completely surround the wound and thick enough to last twenty-four hours is then held

Summary		
Carrel Dakin cases	18% septic	31% septic
Whole series	11% septic	22% septic

with holes punched at one-quarter inch intervals on four sides for a distance of one or two inches from the end.

2 At the time of operation these tubes are placed in the wound in sufficient quantity to allow thorough irrigation. All the holes in the tube should be in the wound or in case of a surface wound requiring irrigation as well none of the holes in the wound. The tubes are lined up sewed to the skin and fastened by adhesive plaster. The tubes should be so placed that puddles are formed in the wounds. At each irrigation the new solution goes to the bottom of the puddle and forces out accumulated debris. The wound is left as widely open as possible.

3 The skin for a considerable distance around the wound is covered by boric ointment compresses made by saturating a fine mesh gauze with ointment. Autoclaving makes the distribution homogeneous throughout the gauze.

4 Cultures and smears are taken with platinum loops from the wound at operation. Smears are then taken every two or three days and stained with methylene blue. The average number of bacteria seen in five high power fields is noted. In the usual septic case the number is more than fifty at first and is noted as "infinity." During the next few days the number will be reduced to perhaps fifteen or ten. When no more than one organism is seen in five fields, the wound is considered sterile. Then,

in place by a towel or swathe the latter being pinned rather than bandaged.

7 The best technique calls for a dark colored solution bottle holding 800 to 1000 cc attached to the bed. This bottle is connected by rubber tubing and glass connecting tubes to each of the smaller tubes in the wound. Every two hours a clamp on the tube is released allowing a measured amount of the solution to flow into the wound. If the bottle is at the proper height and if the skin is properly protected this solution may be given day or night without awakening the patient. However, in this hospital it is impossible to get internes to use the gravity apparatus. Instead they clamp each tube as it emerges from the dressing and cover it with a sterile sponge. Each of the tubes is then filled separately. This is a serious break in an aseptic technique.

8 Five to fifteen cubic centimeters of the solution is given per tube every two hours. Dakin has demonstrated that bacteria will grow in solution more than two hours old. Frequently we have found patients having the instillations regularly during the day but only once or twice at night, and of course these patients have not done well. The first irrigation should be given before the patient leaves the operating room and not wait until the next day.

9 All parts of the dressing except the tubes must be changed daily. Each tube should be flushed out with a syringe. The skin should

be cleansed with neutral soap solution, which in turn should be washed off with salt solution. Irritation of the skin may be relieved by zinc oxide ointment. We see no merit in the use of hydrogen peroxide to cleanse the skin.

10 All material to be used in carrying out this technique and no others should be at the bedside on a cart. Strict asepsis must be used and all material and dressings handled by instruments.

11 A potentially septic wound should be sterile in three or four days. A frankly septic wound should be sterile and ready for a secondary suture or dry dressings in eight to ten days.

12 For large surface wounds it has been found helpful to cover the tubes individually with small pieces of Turkish toweling. This keeps the tubes from moving during the installation. It keeps the débris from filling the holes in the tubing but it does not interfere with the installation of the solution. In other cases it is helpful to use a tube attached at both ends to a Y tube with the holes punched in the central part of the tubing.

SUMMARY

1 This series comprises two hundred and thirty-six compound fractures and dislocations occurring in two hundred and twenty-nine patients. Of these, twenty-two were fractures one week or more old. The end results have been studied in one hundred and sixty-three cases.

2 The method of débridement in use at this hospital and the technique of Carrel-Dakin treatment have been described.

3 A study has been made of the amount of sepsis, disability and permanent deformity developing after treatment of compound fractures by various methods.

4 The incidence of tetanus in the series was 0.48 per cent, of gas bacillus infection none, of persistent bone infection 2.9 per cent.

5 Sepsis followed treatment in 18 per cent of the cases. In the mild puncture wounds this was 65 per cent, while in the cases caused by direct trauma it was 24 per cent.

CONCLUSIONS

1 If treated early and adequately, the average compound fracture caused by indirect trauma is no more serious than a simple fracture. If sepsis develops, the period of disability is prolonged and the end result is not so good.

2 Our results obtained by cleansing the small puncture wound, applying an antiseptic solution and leaving the wound to granulate have been for the most part satisfactory.

3 Compound fractures from direct trauma are far more serious and call for very radical measures. Thorough débridement of a compound wound with adequate irrigation usually prevents the development of sepsis. We believe that some of the smaller wounds may be tightly closed after débridement but that the larger ones

should be left wide open. We do not advocate loose closure or partial closure with drainage.

4 The Carrel-Dakin treatment is a satisfactory method of treating a septic compound wound or in preventing sepsis in a potentially septic wound if the treatment is carried out according to the original published technique.

5 Débridement prevents the development of gas bacillus infection. Gas bacillus serum is not needed as a prophylactic agent.

6 A prophylactic dose of antitetanic serum will usually prevent tetanus, or if tetanus develops, will reduce the severity of the disease.

7 Débridement of the bone ends will usually prevent the death of bone and the resulting formation of sequestra.

8 Our results of treatment by the present methods are quite satisfactory with the exception of the femurs and the bones of the leg. There was too much sepsis in these groups. Radical measures should be used in a larger number of these cases.

DISCUSSION

DR. PHILIP WILSON, Boston, Mass. I have been much interested by Dr. Daland's paper. He has made a thorough study of a large group of cases and a good deal can be learned from it. In considering the results, however, it is important to bear in mind that the patients have been treated by a number of surgeons of varying experience and skill, and that in consequence techniques have differed, and the results from different methods of treatment have not been uniform.

In treating compound fractures several questions arise that require nice judgment. First is the time interval between injury and treatment. When the patients reach the hospital soon after injury we know there is a very reasonable chance of being able to mechanically disinfect the wound by the operation of débridement. What is the time interval before this method becomes impractical and what should we do when the patients reach us in the doubtful period? When they are brought in within the first ten hours I believe there is a reasonable chance of success from débridement. After ten hours the surgeon should decide upon one of two courses, either assume that the wound is clean and protect it with proper dressings, or open it widely on the theory that it is already infected and that the bacteria are too widely disseminated to be influenced by débridement.

A second question demanding good judgment arises in connection with the treatment of the cases with small puncture wounds. We have proceeded on the basis of leaving alone those in which the opening was so small that we didn't believe the end of the bone could actually have protruded, where it simply came to the skin, made an opening, and with drew again. Where the wound was large enough to have permitted the bone to come out we have performed débridement.

You will notice that in Doctor Daland's series there were no instances where the Orr method of treatment was employed. This is partly due to the fact that the study covered the period from 1923 to 1929 before there was much discussion of this method, and also because we have not been very enthusiastic about this method. Perhaps we shall become so in the course of time. Then too, there were very few cases in this group in which immediate plating was done. I think we are now find

ing this a very useful method in certain types of compound fractures. One can perform a débridement, apply a steel bone plate, leave the wound open and splint the fracture, and the presence of the plate has no influence upon the development of infection, nor does it interfere with healing. The plate maintains the reduction and granulation tissue may grow out and cover it, or if not the plate may be removed when consolidation becomes sufficiently advanced.

Finally a word of warning must be said against the injudicious removal of loose bone fragments. I shall always remember a woman with a compound fracture of both bones of the leg who was treated by a young surgeon and a débridement performed. When I first saw this patient there was a considerable gap between the fragments of the tibia with loss of bone substance. The surgeon said that a bone fragment was loose devoid of blood supply, and there was nothing to do but remove it. The patient made a good recovery and never developed any infection; the wound healed by granulation, but there was no union for three years. Three bone grafting operations were performed before success was obtained in bridging the gap and obtaining union. The lesson is obvious. It would have been far better to have retained the loose fragment to serve as a scaffolding for new bone formation even at the cost of a localized infection. We could have dealt with such an infection far more successfully than we did with the final pseudarthrosis.

DR. FREDERIC JAY CORTON, Boston, Mass. I should like to add a word to that. It seems to me that we are getting around to a point where we begin to know something about handling the compound fractures and the results have been getting a good deal better in recent years, but I stepped down here to focus on one thing. It seems to me the results in fractures by direct violence of both bones of the lower leg present the field in which we should work, and I think the results so far are pretty bad, not only in this series but in general, and in general they are a great deal worse than they are at the Massachusetts General Hospital.

It seems pretty clear not only from what Dr. Daland said today but from what we have heard for several years past that the débridement and leaving open of the case doesn't work very well. Dakin's treatment, yes, as it is carried on in Pennsylvania but in all these cases that I know, except the Massachusetts General Hospital, it is rather sketchy and inadequate. Dakin's treatment has to be perfect or it is worthless.

I want to put in a plea for the attempt to close in these cases. In the first place a great many of these cases have ragged wounds and the reason they are not closed is that the wound won't come together. May I say a word in favor of doing plastics to bring them together? You can take a long slash up one or both sides of the wound quite away from the wound and bring the edges together closing tightly enough so that there is no air exposure.

In default of the ability to close it seems to me the Dakin treatment hasn't justified itself very well and I wonder if we are not coming over to protection with grease which is nothing radical, simply protecting the surface and giving a chance for cicatrization under a vaseline layer protecting from air-drying and infection, and unnecessary pockets which will breed infection. This is along a line which we have not done enough of in this country.

We should be able to get better results in the particular cases of lower leg fractures and those are the ones in which we get our calamities.

DR. PIERCE H. LEAVITT, Brockton, Mass. It appeared to me when Dr. Daland was reading the paper, that he was reporting cases from a large hospital where possibly most of the work was done by the house doctors. I think it would be interesting if a series of private cases of the regular visiting staff could be recorded as a method of comparison. Possibly there may not be enough to compare with this series but cases could be collected from members of the staff looking after their own compound fractures and probably giving a little more careful attention than would be possible by a house doctor.

DR. PIER P. JOHNSON, Beverly, Mass. I should like to say a word in connection with what Dr. Wilson said about bone fragment removal. He has touched on an important point, the tendency to remove too many bone fragments and I should like to mention a case I saw some years ago of a boy about nine years old who was run into by an automobile. He had compound fracture of both bones of the leg, the skin wound extending from just below the tibial tubercle to the ankle, and the middle third of his leg was entirely broken into three fragments, completely detached and loose outside of the wound.

It was a question of either amputation or replacing those fragments. I washed them off with salt solution and tied them together in bundles and replaced them between the ends of the bones. It took me about two years to get the final end result and I got a result which was perfect. Although he finally ejected most of the fragments there was reformation of bone without shortening. It was a striking example of what nature will do if you give it a chance.

DR. W. J. MIXTER, Boston, Mass. This is a little far from my particular line but I think that the question of the value of a bone fragment is of distinct interest.

There was one patient I operated on a good many years ago for pituitary tumor. He was operated on by the older technique in which the whole supra-orbital ridge and part of the frontal bone was taken out, with the idea of replacing it afterwards. It was taken out and placed on the table wrapped up in a sterile sponge. At the end of the operation the supra-orbital ridge was found to have been thrown in the bucket by the nurse. It was rather an appalling situation and I was a bit stuck, however, we boiled it up in the instrument boiler for two minutes and put it back. He had no sepsis whatever and the balled bone united perfectly well. This is simply an illustration of what bone will do even when it is badly insulted.

DR. ERNEST M. DALAND. I let the figures 47 per cent sepsis in the bones of the lower leg go without much defense. In my paper I have gone into much more detail as to actual cases and I think you will find results aren't quite so bad as they look because as I say one drop of pus in a stitch-hole has been classified as a septic case even though the result may have been perfect. Some of those cases obviously should have been amputated but a too enthusiastic house officer or visiting man Dakinized them and attempted to get away with it, but it was attempting too much in some cases.

Speaking of plating the fractures there was but one case in the entire series that had a plate in a compound wound and that patient did perfectly well. We have had a number of cases during the last two years not included in the series.

LEUKOPLAKIA BUCCALIS AND KERATOSIS LABIALIS*

BY SOMERS H. STURGIS, M.D.,† AND CHARLES C. LUND, M.D.†

ETIOLOGY

ALMOST twenty years ago Levy¹ wrote that "the interest in the study of leukoplakia lies in the fact that the essentials leading to a practical understanding of the subject have been for many years, and still are, unsettled." Schwimmer²² in 1877 was the first to describe the condition under its present name. During the first decade of the twentieth century the French writers Dancier, Gaucher, Bonnett, Montpelier and others concentrated their attention on syphilis as the principal cause. Although the latter two doubted the exclusive etiological rôle of a specific infection, most French authors agreed with Landouzy² that "the important, determining factor is syphilis,—for syphilis, if carefully searched for, can be verified in the majority of leukoplakias." Kyle³ of Vienna believed that ninety per cent of patients with leukoplakia would be found to have syphilis. However, the prevalence of the descriptive term "smoker's patch" before 1900 shows that tobacco was also recognized as an important contributing factor, and Bettman⁷ stated in 1932 "I have never seen leukoplakia in a patient who has not used tobacco."

Other etiological factors of possible importance have appeared in recent years in the literature. In 1927, Fitzwilliams⁸ reported the first case of leukoplakia of the tongue caused by an electric current, and mentioned the galvanic action of adjacent dissimilar metal fillings in the teeth as a possible cause in other cases. Beecher⁹ in 1928 raised the interesting question of the rôle of food allergy by reporting two cases with chronic leukoplakia who were cured by the removal of certain articles from their diet to which these patients were found sensitive. Others have claimed that hyperacidity of the saliva might constitute an irritating factor of importance over a long period of time. Although no report on the pH of saliva of patients with leukoplakia has appeared in the literature, Sharp¹⁰ nevertheless showed in a series of cases with non-ulcerated malignant lesions of the mouth no variation from the normal salivary pH. It is reasonable to conclude that if this is true of these malignant lesions, it is probably equally true of so called premalignant lesions of the buccal mucosa. King and Hamilton¹¹, publishing observations on eighty cases in 1931, called attention to the fact that, like some other

diseases, leukoplakia seemed to progress faster in diabetic patients. Bloodgood^{4, 5, 6} repeatedly stressed the rôle both of jagged, rough teeth and of chronic infection in dirty mouths, concluding that the irritation from these causes together with that from tobacco explained the etiology of the disease. Concerning bacterial action alone, as in chronic gingivitis or Vincent's infection, James¹³ is quoted by Fox¹⁴ as saying "I have found no other cause than dental infection" for leukoplakia. In this connection, Hollander et al.¹⁵ remark that leukoplakia is also found in the esophagus, vagina, kidney pelvis and bladder mucosa which can hardly be attributed to tobacco, galvanic currents, rough teeth, etc., and in these cases—when the absence of syphilis is proved—the irritation of the mucous membrane from low-grade sepsis alone appears to be the cause. Lain¹² emphasized the importance of mechanical irritation from ill-fitting dentures as an etiological factor, and showed also that the presence of mercury sulphide and sulphur in overcolored or undercured Vulcanite dental plates may cause chemical irritation of the mucosa. He further pointed out that improperly vulcanized plates may be of sufficient porosity to allow a deposit of food particles which then become a chronic source of bacterial fermentation. The work of McCarrison and Guerin (both quoted by Orr¹⁶), tends to show that epithelial tissue responds characteristically with keratinization, round cell infiltration, etc., to a deficiency of vitamin A. Orr, reporting oral cancer cases among the Indian betel-nut chewers, correlates the low vitamin diet of the Travancore coolies with the high per cent of oral cancer confined to this district and Geschickter¹⁷ has recently suggested that the same deficiency might be the underlying factor in many cases of leukoplakia of the mouth.

Thus, in summary, the following are the more important factors that have been suggested as the sole or participating cause in production of leukoplakia of the mouth at one time or another: syphilis, tobacco, chronic infection, mechanical or chemical irritation from rough teeth, ill-fitting, or poorly made dentures, electro-galvanic currents, vitamin A lack, food allergy and hyperacidity. The essentials leading to an understanding of this disease would appear to be as unsettled as when Levy wrote his article in 1915.

Concerning the etiology of cancer, however, both Lund¹⁸ and Warren and Gates¹⁹ have presented evidence of a systemic factor in this disease. Although they all concede the importance in many cases of a local, irritating factor, they have recently proved that there may also

*From the Cancer Commission of Harvard University. This work was made possible by grants from anonymous donors and from the Delamar Mobile Research Fund.

be "a predisposition or susceptibility to cancer in certain persons, or the action of some factor favoring the development of malignancy, the nature of which is unknown"¹⁸ Likewise, as suggested by Hollander¹⁹, an understanding of leukoplakia may eventually recognize the same two categories of important factors—systemic and local. The systemic factors might include (1) syphilis, (2) vitamin A lack, (3) hereditary predisposition to atrophic and degenerative change closely allied to a possible cancer susceptibility, and local factors might include (1) tobacco, (2) chronic infection, (3) bad dental status, (4) electric currents. It is certainly true that the presence of any one of these factors even in excess does not necessarily bring about the development of leukoplakia. Perhaps one of the secondary, irritative factors in the presence of one of the primary, systemic factors may explain the etiology of the disease in a majority of cases. Unfortunately, we have no method to test for vitamin A lack or for cancer susceptibility. Persistence of the premalignant lesion in the absence of syphilis or any of the secondary local factors listed above is the best indication that we have of the presence of one of these primary, systemic causes. Such persistent leukoplakias may be looked on, as in Levy's concluding words, "as a warning" of malignant disease.

CLINICAL STUDY

For a clinical description of leukoplakia of the oral mucosa, the article on this subject by Hollander, Permar and Shonfield¹⁸ gives an excellent and detailed review of the subjective and objective symptoms, the pathology, and the differential diagnosis of this disease. The following conditions should be considered in making such a diagnosis: (1) Lichen Planus, (2) Syphilis—both the mucous patches of the secondary form and the sclerosing glossitis of the tertiary form, (3) Aphthous Stomatitis, Thrush and Vincent's Infection, (4) Lupus Erythematosus, (4) Glossitis Migrants.

Keratosis of the lip—a closely allied condition—is a dry, crusted, superficial lesion, generally well-defined but at times with no definite border, so that adjacent areas may be so confluent as to involve the entire lip. In depth it varies from a thin milky or greasy film spreading over the lip and resembling a leukoplakia that has become dried and slightly crusted through exposure, to a thick, horny lesion elevated by the progressive heaping up of the stratum corneum to one or two millimeters. These hard inelastic lesions are apt to fissure and ulcerate and the differentiation from early epidermoid carcinoma becomes clinically difficult. Lesions on the lip are found in frequent association with keratoses on the face, neck and other exposed parts, not rarely lesions are situated at the mucocutaneous junction, but for the most part they are confined

within the vermilion border. The lower lip appears to be more frequently affected than the upper lip. In the differential diagnosis the following should be borne in mind: (1) Herpes Simplex, (2) Syphilis—the primary sore, the secondary mucous patches and the tertiary atrophic changes, (3) Lupus Vulgaris and Erythematosus and (4) Chapping and cracking of the lips following exposure to cold and associated at times with the habit of moistening the lips.

The characteristic features of keratosis of the lip are as follows: (1) appearance at or after middle life, (2) chronicity of the lesion, (3) dryness and crusting of the lesion unless cracks and ulcerations have already appeared, (4) confinement to the mucous membrane of the lips—rarely confluent with lesions over the cheeks or chin.

MATERIAL

This study is based on the records of five hundred and twenty patients who entered the Collis P. Huntington Memorial Hospital clinic between 1918-1926 with leukoplakia or keratosis of the mouth or lips. Keratosis of the lips was included as well as leukoplakia of the mouth or lips since both lesions are so frequently encountered together with the same etiological factors at work and often so confluent that differentiation becomes difficult. One hundred and forty-two of these patients entered between 1918-1921 and three hundred and seventy-eight between 1921-1926. It is probable that a number of cases seen at the clinic for oral cancer during the first three years were not carefully examined for leukoplakia since Simmons^{20, 21} finds the recorded incidence of leukoplakia in cancer cases at that time to be only fourteen per cent, whereas in the next three years, 1921-1923, when a more thorough examination of the buccal mucosa was instituted, he finds the incidence in a similar group of cases to be twenty-five per cent. The records were first codified and recorded on punch cards according to a system outlined by Lund²⁰ in a previous report. The

		520

cards were then divided into groups relative to the development of cancer (see table I). Of these five hundred and twenty cases, two hundred and twenty-two had evidence of cancer be-

fore, or at the time of admittance. Two hundred and ninety-eight patients entered the clinic with no evidence of cancer on or before entry, two hundred and sixty-one or eighty-eight per cent of these did not develop cancer, while thirty-seven or twelve per cent did develop malignancy during the period of observation.

INCIDENCE OF CANCER

The incidence of cancer in leukoplakia of the mouth was said by Mantilla (quoted¹⁴) to be about thirty-two per cent in a total of five hundred and sixty-six cases collected from the literature up to 1901. King and Hamilton¹¹ report six per cent in their series of eighty cases, but include another thirty-two per cent in a group of "definitely precancerous lesions." In the present study twelve per cent of the group of two hundred and ninety-eight patients who had no malignancy before or at entry later developed cancer. This incidence does not necessarily prove that leukoplakia and keratosis are premalignant lesions. To prove the latter, it is necessary to know the incidence of cancer in a group of normal individuals of similar age and under observation for a similar period of time. This calculation has been made by using tables previously published by Lund¹⁹ and based on the Massachusetts Death Rates for males during the years 1920-1930. It is possible to determine by these tables the numbers of deaths from intercurrent disease, from intercurrent cancer, and from intercurrent buccal cancer that should occur on the basis of chance alone.

In table II are grouped the forty-nine cases in the present series that developed cancer after entry according to location of the cancer. Twelve cases developed double malignancy, the first of which occurred before entry to the clinic. These were disregarded in making the calculations. The details of the remaining thirty-seven cases are given in tables XIV, XV, XVI, XVII and XVIII which may be found at the end of this report.

TABLE II

DISTRIBUTION OF CANCER AFTER ENTRY—49 CASES

I	Two cancers, one before entry		12
II	Cancer after entry only		37
		Cases	Cancer Deaths
	One buccal cancer (see table XIV)	21	10
	Two buccal cancers (see table XV)	4	2
	Skin cancer only (see table XVI)	3	0
	One non buccal cancer (see table XVII)	7	7
	Two cancers, one non buccal (see table XVIII)	2	1

In table III the deaths calculated from the death rates for a control group are contrasted with the deaths in the series of cases under study. It is seen that fifty-three deaths from intercurrent disease other than cancer may be

TABLE III
LEUKOPLAKIA AND KERATOSIS
Expectancy of Cancer in 298 Cases

	Non Cancer Deaths	Buccal Cancer Cases	Deaths	Other Cancer Cases	Deaths
Calculated	53		1		9
Actual	59	25	12	12	8

predicted in a group of two hundred and ninety-eight normal individuals in circumstances similar to those of the two hundred and ninety-eight patients studied. Actually there were fifty-nine non-cancer deaths. By calculation, there should have been one buccal cancer death and nine deaths from cancer in other organs. Actually, there were twelve buccal and eight other cancer deaths in the group of cases under study.

The methods of calculation used here are not absolutely accurate. In every step, however, a conservative position was taken, so that the resulting ratios probably underestimate rather than overestimate the difference between the calculated and the actual development of cancer. Nevertheless, the above figures clearly demonstrate that patients with leukoplakia or keratosis of the mouth or lip develop buccal cancer at least twelve times more frequently than chance alone would predict. The term "pre-malignant" may justifiably be used, therefore, to describe these conditions. In this series, however, patients with these premalignant lesions appear to run no greater risk of cancer in some other organ than individuals without such lesions.

The total series of five hundred and twenty cases was analyzed to determine the significance of age and sex, and of the three more important etiological factors—tobacco, teeth and syphilis. The end-results of treatment in the two hundred and ninety-eight cases that showed no evidence of cancer at or before entry were then studied in relation to location, duration and extent of the premalignant lesion.

AGE

Leukoplakia and keratosis are diseases of late middle life, with thirty per cent of the cases in this series coming between fifty-five and sixty-five, and the average age being fifty-seven and one-half years. Chart I shows graphically the age of the five hundred and twenty cases divided into five year columns and recorded by per cent. In this chart, a series of eleven hundred and thirty-one patients entering the hospital with cancer of the mouth are similarly divided for

comparison The curves of the two groups are closely parallel, with the premalignant cases showing a little more tendency to fall in the younger age divisions The average age of the malignant patients was sixty and seven-tenths years

SEX

Ninety-one per cent of the patients were males Other authors^{11, 14} confirm the preponderance of men with leukoplakia of the mouth A similar proportion of patients with cancer of

CHART 1

COMPARISON OF AGES IN
PREMALIGNANT AND MALIGNANT SERIES

the mouth are found to be males In his interesting comparison of cancer of the mouth in the two sexes, Taylor²¹ emphasizes the etiological importance of tobacco, teeth and syphilis in relation to the incidence of these factors in each sex Disregarding cigarette smoking as probably innocuous to the buccal mucosa, and referring to cigars pipes and the chewing habit only, "the almost universal use of tobacco among men" he says "may account in large measure for the greater incidence of cancer of the mouth in men than in women" Although bad teeth are a conspicuous etiological factor for both sexes, "men cling to bad teeth longer than women, while the latter provide themselves much more often with dental plates after earlier extraction" In conclusion, Taylor finds syphilis to be a less conspicuous etiological factor in the female group than in the male group of lingual cancer cases

Similar statements concerning the different incidence in men and women of the tobacco habit, bad teeth and syphilis, probably pertain to premalignant disease of the mouth, and explain why, in the present series of five hundred and twenty cases four hundred and seventy-three were men

TOBACCO

Almost all authors agree in finding the use of tobacco in from eighty to ninety-five per cent of their patients Of the four hundred and twenty-one reports on tobacco in the records of the group under study, ninety-four per cent used tobacco in some form (table IV) Concerning

TABLE IV

	Tobacco		No Tobacco	
	Cases	Per Cent	Cases	Per Cent
Leukoplakia	244	96	10	4
Keratoses	150	90	17	10
	394	94	27	6

the type of tobacco used there were only one hundred and ninety-five records that contained sufficient data for tabulation The use of cigars or cigarettes and the habit of snuff-chewing are recorded so infrequently that they have been disregarded In the remaining cases, it is interesting (see table V) that among the leukoplakias

TABLE V

TYPE OF TOBACCO IN USE—195 CASES

	Pipe	Chewing Tobacco
Leukoplakia	12%	36%
Keratoses	31%	19%

the ratio of pipe to chewing tobacco in use is one to three while among the keratoses this ratio is almost reversed

This tends to confirm Taylor's statistics which show a localization of the buccal lesion in relation to those areas of mucous membrane most constantly exposed to the irritation of tobacco Keratotic lesions, confined to the lips in these cases, were associated with pipe-smoking almost twice as often as with tobacco chewing Leukoplakias, however, only twenty per cent of which were located on the lips were found associated with tobacco-chewing three times as often as with pipe-smoking

TEETH AND DENTURES

As a corollary to the statement that tobacco, bad teeth and syphilis are the three most important etiological factors, it may be added that leukoplakia and keratosis are diseases of the poorer classes Perhaps the most conspicuous class difference will be found in the care of the teeth Bloodgood⁴, Hazen and Eichenlaub²² and many others have emphasized the importance of such care In an analysis of the dental status of the cases under study, it may be assumed "that edentulous patients had periods of more or less protracted caries and pyorrhea before submitting to total extraction,"²¹ and such cases may be included with the group showing bad teeth at entry, for they have already under-

gone long exposure to dental trauma and infection. Concerning plates and dentures, these must fit accurately in order not to irritate the mucous membrane, frequent adjustment is therefore necessary. They must be of non-irritating material, Lain¹² has shown the results of cheap or poorly made dentures. They must also be kept clean. Frequent adjustment and plates made of high-grade material are not generally within the means of the clinic patient, cleanliness is often at a premium. It is not unreasonable, therefore, to include those cases that had plates or bridge-work on entry as well as their premalignant lesion of the oral mucosa, among the group having "bad dental status."

In this series, there were two hundred and fifty reports on the condition of the teeth. These have been summed up in table VI. Since there is a record of the dental condition of only one-half of the total of five hundred and twenty cases, and since it is probable that clean mouths were not recorded so often as dirty mouths,

TABLE VI
DENTAL STATUS IN 250 CASES

		Leukoplakia		Keratosis	
		Cases	Per Cent	Cases	Per Cent
Bad	No teeth	61	30	6	14
	Bad teeth	83	40	26	60
	Plates or bridge work	48	22	6	14
	Total	192	92%	38	88%
Good		15	7	5	11

the percentage given above for those with bad dental condition is undoubtedly high, especially is this true of keratosis of the lip. However, at least sixty per cent of the total number of patients with leukoplakia—one hundred and ninety-two out of a total of three hundred and twelve—may be assumed to have suffered from bad dental hygiene.

Solomon and Reinhard²⁴, working at the New York State Institute for Malignant Disease, Buffalo, N. Y., have recently reviewed the literature on galvanic currents produced by dissimilar metals used in fillings, plates and other bridge-work. The work of Palmer in 1876, and of Chase and Grant (all quoted by ²⁴) shows that the soft tissue response to these currents was being carefully considered at the time when the study of leukoplakia was just beginning. Indeed, the latter wrote that "there are many who carry (amalgam fillings) with impunity because of their lack of susceptibility, and no man can tell before trial who can and who cannot bear them." Recently Ewing²⁷ has recognized the soft tissue irritation "from electrical discharges from dental plates" as a possible factor, with other oral irritation, in the etiology of cancer in the mouth, and in the

work of Fitzwilliams⁸, Fraser²⁵, Ullmann²⁶, and Hollander¹⁵ there is presented further evidence of the presence of such a current wherever even minute quantities of dissimilar metals are used in the mouth. This current is not found in mouths in which only fillings of the same electrical potential are used. In three hundred consecutive cases of dissimilar metallic dentures, Lain²⁸ has reported leukoplakia adjacent to the dentures in twenty-one per cent, and "either subjective or objective electrogalvanic phenomena" in seventy-one per cent. Solomon and Reinhard conclude, however, "Observation shows that most mouths apparently tolerate such action without ill effect. In practical interpretation of the relationship of galvanic action to production of oral lesions, we must stress the scarcity of objective and subjective symptoms in view of the large number of restorations present in most mouths." No work was done on such galvanic action in this clinic during the years 1918-1926 which include the cases herein reported.

SYPHILIS

In the literature on leukoplakia the apparent tendency has been to view as of less and less importance the etiological significance of syphilis. Thus Fourmer (quoted by Bettman¹) had reported eighty per cent luetics among three hundred and twenty-five cases with leukoplakia, Max Joseph (same) found thirty-five per cent in one hundred cases. In 1922, Hazen and Eichenlaub²² excluded syphilis in all but thirty per cent of their patients, and King and Hamilton²¹, reporting eighty cases of leukoplakia in 1931, found but ten per cent syphilitic and concluded that it played "a minor rôle, in that all of this group had bad teeth and smoked excessively." Elliott and Stookey³, however, considered "the presence or absence of leukoplakia involving the entire mucous membrane" a valuable piece of evidence in the diagnosis of neurosyphilis. They found but one normal buccal mucosa in fifty neurosyphilitics.

In this series, there were sixty patients in whom a positive Wassermann reaction or definite past history of infection made the diagnosis certain. Fifty-five or seventeen per cent of the leukoplakias, and five or two per cent of the keratoses. Wassermann reactions, however, were done at this time only on the suspicious cases in this clinic—two hundred and forty-two of them, thus out of two hundred and forty-two tested cases, the leukoplakia patients show twenty-seven per cent positive reactions and the keratoses thirteen per cent. It may properly be concluded that syphilis is of minor importance in the etiology of keratosis of the lip. The true per cent for leukoplakias irrespective of location, probably lies between seventeen and twenty-seven per cent for this series (table VII).

our studies of syphilis in cancer of the traser²² and Lund²³ have presented evidence that syphilis was an important etiological factor in cancer of the tongue alone. Similarly, syphilis is found to be etiologically significant

TABLE VII
INCIDENCE OF SYPHILIS

	Total	Evidence Lues	Total Wasser- manns	Evidence Lues
Leukoplakia	312	55 17%	204	55 27%
Keratoses	208	5 2%	38	5 13%
Total	520	60	242	60

only in leukoplakia of the tongue—as mentioned in a report by Goodale²² in 1900. Among the leukoplakias that did not develop cancer (see table VIII), sixteen per cent of the tongue lesions showed evidence of syphilis. In the group of leukoplakia patients that did develop cancer

TABLE VIII

SYPHILIS IN CASES OF LEUKOPLAKIA THAT DID NOT DEVELOP CANCER

Location of Leukoplakia	Total Cases	Evidence of Syphilis	
		% of Total Cases	% of Tested Cases
Tongue	25	16%	24%
Rest of mouth	51	6	13
Lips	19	5	12
Whole mouth	7	0	0

at some stage of their disease (table IX), forty-eight per cent of the tongue cases had syphilis

TABLE IX

SYPHILIS IN CASES OF LEUKOPLAKIA THAT DID DEVELOP CANCER BEFORE, DURING OR AFTER ENTRY

Location of Leukoplakia	Total Cases	Evidence of Syphilis	
		% of Total Cases	% of Tested Cases
Tongue	45	48%	57%
Rest of mouth	93	5	7
Lips	43	9	13
Whole mouth	26	24	28

In this cancer group, leukoplakia lesions involving the mucous membrane of almost the whole mouth also showed a high percentage of luetics. Bloodgood⁴ has reported thirteen per cent positive Wassermann reactions in all lesions of the tongue—both benign and malignant—as compared with three per cent positives in all other lesions of mouth.

The present study confirms previous work

that syphilis plays an important rôle in the etiology of leukoplakia of the tongue, and further that it is found three times as often in those tongue lesions that developed cancer as in those that never developed cancer. It is probable that the reason for the contradictory estimates of the incidence of syphilis in the literature on leukoplakia may be due to the fact that the location of the lesion was not taken into account. There were only fifteen syphilitic patients among the cases showing no cancer at entry. All of these received specific treatment and only one later developed cancer. This does not prove, however, that antiluetic treatment given after the leukoplakia has developed is of use in the prevention of cancer in these cases. The series is too small.

END-RESULTS OF TREATMENT

For the study of end-results the material included only those cases that had no oral cancer either before or at the time of their entry, and that were kept under observation for five years or more. The two hundred and forty-eight cases that made up this group were divided into three classes as follows: (1) The cures, one hundred and fifty-eight or sixty-three per cent,—those that responded to treatment and did not recur within five years. (2) The persistent cases, sixty-five or twenty-six per cent,—those that were never relieved as well as those that responded but recurred within five years. (3) The cancer cases, twenty-five or ten per cent,—those that developed malignancy in or contiguous to their premalignant lesion during the period of observation. These cases were studied according to the location, duration and extent of the original lesion. Unfortunately the subdivisions resulting from such a study contained very small numbers of cases, far too small in many instances to be valuable from a statistical point of view. The results may serve to indicate to a certain extent, however, the relative importance of the factors under consideration.

During the years 1918-1926, a small number of cases were given no treatment other than an attempt to institute a hygienic régime, which included the cessation of all use of tobacco, extraction or smoothing down of rough teeth, the establishment and maintenance of oral cleanliness and adjustment of dentures. A majority of the cases, however, were treated on entry to the clinic with radium unless they were clinically suggestive of malignancy. On the borderline cases, an operative procedure—either electrocoagulation diathermy or surgical excision—was used alone, or followed by radiation. Other cases in which both operation and radiation were used represent surgical attempts to salvage unsatisfactory radiation results.

Table X shows end results in relation to treatment received. Forty per cent of the small group placed only on a hygienic régime were cured. The results from operation or radiation alone for both leukoplakia and keratosis were roughly comparable. The poorer results in the group requiring both operation and radiation may be ascribed to the persistence, or suggestive malignancy of these lesions rather than to the more vigorous treatment received.

In comparing end results of the leukoplakia

TABLE X
FIVE YEAR RESULTS OF TREATMENT
LEUKOPLAKIA AND KERATOSIS—248 CASES

Treatment	Total Cases	Lesion "Cured"	Per sisted	Devel oped Cancer

Operation	24	79	13	8
Radiation	182	69	24	7
Both	22	54	26	20

group with the results of the keratoses obtained by the different methods of treatment, there is a significant difference only in the group of one hundred and eighty-two patients treated with radiation. Under this treatment, seventy-five per cent of the keratotic lesions were cured, while only forty-two per cent of the leukoplakias responded without recurrence within five years.

LOCATION AND END RESULTS

The location of the premalignant lesion was studied in its bearing on the end results, irrespective of the treatment received. The fact that a syphilitic basis for leukoplakia is frequently found in tongue cases (table VI) leads one to expect that the end-results from tongue lesions

TABLE XI
FIVE YEAR RESULTS IN RELATION TO LOCATION—
248 CASES

Location	Total Cases	Lesion "Cured"	Per sisted	Devel oped Cancer
*Leukoplakia				
Tongue	28	56%	33%	10%
Mouth	25	53	34	13

Total	105	53%	33%	13%
Keratosis				
Lips	143	75%	16%	8%

*All cases with both leukoplakia and keratosis included with leukoplakia.

would be poorer than the others. That this does not appear to be so (table XI) may easily be due to the statistical inaccuracy of conclusions based on such small numbers of cases. This table shows a surprising uniformity of end-

results in relation to the location of the leukoplakia lesions.

DURATION AND END RESULTS

Leukoplakia and keratosis are typically lesions of great chronicity. Fox¹⁴, for instance, gives an average duration of eight and seven tenths years. It is difficult accurately to gauge the duration of the disease from the records because of the indefiniteness of onset of subjective symptoms. However, in order to ascertain the relation of duration of the condition before treatment in the clinic to end results, the cases have been divided into five duration periods on the face value of the patient's story, viz, (1) Under three months' duration (2) Three months to one year (3) One to two years (4) Two to five years (5) Over five years. The cases falling into each duration period have been recorded according to the per cent found in the cured group, the persistent group and the cancer group. (See table XII.) There is found no correlation between

TABLE XII
FIVE-YEAR RESULTS IN RELATION TO DURATION
BEFORE TREATMENT

LEUKOPLAKIA AND KERATOSIS—235 CASES

Duration	Total Cases	Lesion "Cured"	Per sisted	Devel oped Cancer
Under 3 mos	51	60%	21%	19%
3 12 mos	104	77	25	7
12 yrs	32	70	15	15
25 yrs	27	52	37	11
Over 5 yrs	21	67	39	4

the end results and the chronicity of the lesion before entry to the clinic, in the persistent group only there is found to be an increase in per cent of cases in the longer duration periods. Of the two hundred and thirty-five records available for this study, one hundred and eighty-seven or eighty per cent gave a story of under two years' duration from the onset of subjective or objective symptoms to the first treatment in this hospital, the average for the whole group being one and one-half years.

EXTENT OF LESION AND END-RESULTS

Extensive and diffuse leukoplakias involving a large part of the buccal mucosa as well as keratoses spread widely over one or both lips offer a difficult therapeutic problem. At the time of this study, these extensive lesions were generally given multiple applications of radium emanation, supplemented often—in the leukoplakia group—by monopolar desiccation or excision. This treatment, however, appears to have been inadequate. In table XIII, the two hundred and ten cases that contained sufficient data for tabulation have been divided by size

into three classes as follows Small, those lesions not over 0.5 cm. in diameter, medium, 0.6-2 cm., large 2.1+ cm

TABLE XIII

FIVE YEAR RESULTS IN RELATION TO SIZE OF LESION
LEUKOPLAKIA AND KERATOSIS—210 CASES

Size of Lesion	Total Cases	Lesion "Cured"	Persisted	Developed Cancer
Small, 0-0.5 cm.	65	75%	22%	2%
Medium 0.6-2 cm.	79	66	26	8
Large, 2.1+ cm.	66	49	30	14

The figures refer to the per cent of each of these size groups that was cured, persisted or developed cancer. It is seen that the highest per cent of persistent and of cancer cases is found in the "large", or more extensive group of lesions. Some authors have advised against any attempt to treat leukoplakias involving wide areas of mucosa with radiation. The figures presented in table XIII may be considered evidence in support of this view. It is probable that radiation had little influence on the end-results of the diffuse and widespread lesions. The results of both leukoplakias and keratoses over 2 cm. in diameter were equally poor.

PRESENT METHODS OF TREATMENT

In every case of leukoplakia or keratosis of the mouth or lip now entering the clinic for the first time, an effort is made first to eliminate all local factors of irritation. Emphasis is placed on the following: (1) Tobacco. Except for a moderate use of cigarettes, cessation of other forms of tobacco is strongly urged. (2) Teeth. Removal of rough and jagged stumps or of teeth worn to a sharp edge is advised, especially when such teeth are near the lesion where a number of teeth are in a condition of hopeless decay, the patient is urged to enter the hospital for a total extraction. (3) Dentures. A careful examination is made of all permanent caps, crowns and bridge-work. Sharp edges are smoothed, apparatus that is suspiciously near an irritated lesion of the mucosa is removed when possible. If plates are in use, they are temporarily discarded where there is any evidence of irritation of the soft parts. If dissimilar metals have been used in fillings or dentures, the amount of galvanic current flowing between such metals is entered in the record. A consistently high current in successive tests or one flowing between metals adjacent to the lesion, is considered a sufficient reason for substitution of one of the metals with cement or other non-conducting material, or removal of the offending denture. (4) Oral Hygiene. An attempt is made to institute a routine of oral cleanliness. If Vincent's infection is found, it is treated. Pyorrhea and gingivitis are treated with sodium perborate and milk of magnesia mouth washes.

These measures are adopted in all cases of leukoplakia and keratosis. Further treatment depends upon the location, extent and progression of the lesion. Discrete keratoses of the lip respond satisfactorily to a single application of radium emanation used in bare steel needles in this clinic, without any filtration, a dose of three to ten millicurie hours being generally sufficient. If the lesion is heavily crusted or cornified, the radium is applied at a distance of 1 cm. Diffuse, extensive keratosis covering the whole lip may be treated, when superficial, with radium emanation moved back and forth over the lip. If the lesion is thickly crusted, however, good results are obtained by the use of from two to four thousand r units of high voltage x-ray, screened with 0.12 to 0.25 millimeter of copper. If the lesion persists, or if it becomes fissured, ulcerated, or acquires an indurated base, surgical excision with a wide margin is done.

A small discrete leukoplakia, if persisting or recurrent three months after the institution of the general measures outlined in the first paragraph, is destroyed by electro-desiccation under novocain.

If the leukoplakia is extensive, and persistent or recurrent after the removal of all local irritating factors, the presence of a systemic factor is strongly suspected. (1) Syphilis. In all new cases entering the clinic a blood specimen is routinely taken for Wassermann, Hinton and Kahn reactions. When syphilis is proved by these tests, appropriate measures are instituted for its control. (2) Vitamin A lack. On the purely theoretical grounds that vitamin A lack may be causal in some cases in which the entire buccal mucosa appears to be devitalized, highly irritable and predisposed to the constant formation of leukoplakia, large doses of vitamin A are given orally for a test period of three months. The results of this treatment, however, are as yet insufficient to justify any conclusions. (3) Susceptibility to cancer. In the presence of continued persistence or recurrence of leukoplakia, the patient is regarded as a case in whom an unknown factor has predisposed the buccal mucosa to malignant development. Frequent observation of the condition becomes imperative. When the lesion becomes thickened, cracked or fissured, electrosurgical excision is promptly done. Radium and x-ray are no longer used in this clinic to treat extensive leukoplakias. Experience shows that although there may be a good response in turn to each local application of radium, yet the whole oral mucosa cannot be treated at once, and new lesions form in other locations as fast as old ones are destroyed. Poor results in these cases must be accepted, prognosis will depend upon the stage at which an early cancer is recognized and eradicated. The patient must, therefore, be impressed with the fact that the most important element in the proper treatment of his condi-

tion is his coöperation and willingness to return every three months or less for observation in the clinic

SUMMARY

A number of varied and unassociated factors are recorded as having appeared in the literature on the etiology of leukoplakia buccalis. These have been grouped into systemic and local factors. In an analysis of the incidence of cancer in five hundred and twenty cases of leukoplakia and keratosis of the mouth and lip seen at the Huntington Memorial Hospital, figures are presented that justify the contention that these are precancerous lesions. The three most important etiological factors have been analyzed in this group of cases. The bearing of location, duration and extent of the premalignant lesion on the end-result of treatment in two hundred and forty-eight selected cases has been presented with the full realization that conclusions must be guarded when based on such small numbers of cases. The present management and methods of treatment of these cases in this clinic have been briefly outlined.

CONCLUSIONS

- (1) Leukoplakia buccalis and keratosis labialis are definitely precancerous lesions
- (2) Bad dental hygiene and the use of to-

bacco are both almost universal and equally important as etiological factors in leukoplakia and keratosis of the mouth and lip

(3) Syphilis is found in about thirty per cent of patients with leukoplakia of the tongue but it is of minor importance in all other locations of this lesion

(4) In the series of cases studied, the duration of the lesion appears to have no prognostic significance. Similarly, the duration of the lesion before treatment has apparently no bearing on the results of treatment.

(5) The size and extent of the lesion definitely influence the prognosis on the type of treatment received between 1918-1926 in the clinic of the Huntington Memorial Hospital.

(6) Extensive leukoplakias involving large areas of the buccal mucous membrane do not respond well to radiation. If the lesion persists after removal of all irritating factors, the patient must be kept under constant observation and prompt electrosurgical excision should be done of any areas showing suspicious evidence of cancer.

The authors wish to acknowledge the careful and painstaking assistance of Miss Hilda M. Holm in abstracting the records, and the advice and assistance of Dr. C. C. Simmons and Dr. G. W. in preparing this paper.

OPERATIVE SURGERY IN THE PULMONARY TUBERCULAR*

BY FRANK H WASHBURN, M D †

WHILE the fundamental principles of surgery are unvarying wherever applied, surgical procedure may properly be modified by dyscrimism, systemic infections and specific diseases that are apart from conditions for which operation may be indicated. Thyroid disease, diabetes, hypertension, toxemia resulting from urinary obstruction, etc., each call for special modifications of procedure in preoperative preparation, anesthesia, technique, and after-care. This is equally true of tuberculosis. Pulmonary tuberculosis is variant not only because it is tuberculosis, but because of involvement of the respiratory system.

In diagnosis, in the subject of active advanced disease, we may find a clouding of the picture. This may be particularly true in cases of acute and subacute infections. We have learned to discount the occasional absence of marked leukocytosis and abdominal rigidity in acute peritoneal cavity disease. Sometimes pain and tenderness appear less than in the average patient similarly afflicted, when keen observation only can appreciate the acuteness of onset, in one carrying the toxic manifestations of pulmonary tuberculosis. The differentiation of acute appendicitis and other infections involving the peritoneum, and tubercular invasions or metas-

tases, may present a difficult diagnostic problem. Here the knowledge of the previous blood picture, always available in the sanatorium patient, is a distinct aid.

Preparation should be meticulously careful in the presence of active disease, and measures should be taken toward avoidance of psychic shock. This becomes easier when operation is to be performed in the sanatorium, but if the patient has been moved to another institution, to new surroundings and among different and strange personnel, care ought to be exercised in the suggestions of initial contact. Morale, so important to the end-results in operative surgery, is particularly so in this field. The toxic patient is infected readily making scrupulous preparation of the skin important.

Selective anesthesia we consider especially important. Could an anesthetic be chosen that would produce complete analgesia and at the same time prevent the effects of traumatism from reaching the cells of the central nervous system, if it would not contribute to surgical shock or would tend to prevent it, if it would not diminish or abolish the coughing or swallowing reflexes, or irritate the bronchial mucosa, and if its effect upon the vital organs, as the liver, kidneys, and heart, were not injurious, the task would be simple. This we cannot do, for ideal anesthetics are yet to be discovered.

Local infiltration with ample amounts of dilute procaine solutions, whenever practical, is safest and most desirable. Regional anal-

*Read before the Worcester District Medical Society at the Rutland State Sanatorium in the Symposium on Pulmonary Tuberculosis on October 11 1933

gesia, by nerve blocking, in certain areas meets the requirements nicely. One of the best examples of this is cordal and transsacral injection in anal and rectal procedures. Where the work is to be done below the level of the diaphragm and infiltration is impractical, in our opinion, spinal block best meets the indications with, however, due regard for the usual contra-indications to this form of anesthesia. General anesthesia with all its objectionable features, in pulmonary surgery is a better choice than spinal for operations upon the upper portions of the body. Ethylene gas, nitrous oxide and if necessary, even ether may be used. Narcotics and basal anesthetics should be used to relieve apprehension and lessen the amount of drugs by inhalation and the "Anocel-Association", technique of Crile, has a logical place in this field. Avertin is a desirable choice occasionally, particularly where a quiet respiration is desired. One of our objections to its use is the abolishment of cough and swallowing reflexes. It appears to be the most desirable of all basal anesthetics from the patient's standpoint. The general anesthetics, particularly ether, of themselves increase the burden and contribute to shock. In this fact lies a greater objection than in any local effect upon the bronchial mucosa, however much that may be. A skilled anesthetist is highly desirable. Care should be exercised in diagnosis to avoid unnecessary operations. Gentleness of technique is especially indicated, for the healing processes of the toxic tubercular are certainly far below the normal and reasonable speed in operating, particularly where general anesthesia is used. Spinal anesthesia is particularly an aid to rapid work and avoidance of tissue injury. Operations that may be done in multiple stages sometimes may be successfully thus done where otherwise shock might prove serious. Shock and infection are certainly much more facilitated in the tubercular than in the normal. Infected tissue must be amply drained and re-opening of wounds, sloughing edges, and even indolent ulceration may be avoided only by scrupulous care. Intestinal fistulae more often follow operations where incision or injury to intestine has been done than in the non-tubercular patient. This fact is to be kept in mind when dealing with conditions involving the bowel.

Pregnancy in the subject with pulmonary tuberculosis has served to annoy tuberculosis specialists, obstetricians and surgeons alike since the statement of DuBois, many years ago, that "If a woman threatened with phthisis marries she may bear the first accouchement well, the

second with difficulty, the third never." That therapeutic abortion may be indicated in the case of pulmonary disease is undoubtedly perfectly true but it is not our purpose to define its indications. However, the mere diagnosis of tuberculosis does not justify abortion in our opinion. The definition of indications in a given case must necessarily rest to a large extent upon the physicians and tuberculosis specialists. Operation should never be done except with ample consultation with obstetricians and tuberculosis specialists, and then the operator should still reserve the right to form an opinion and consult his conscience before proceeding to evacuate the uterus. It will perhaps become his duty occasionally, but he must be wary of the urge he may meet to operate where definite necessity does not obtain. Children are born of tubercular mothers without apparent maternal injury sometimes and the average surgeon cannot usually alone determine when that happy outcome may result.

Delivery at term also presents an important problem. Keen obstetrical judgment is important and the prophecy as to whether labor will be easy or difficult places real responsibility upon the accoucheur. Cesarean section competently performed is probably preferable to "watchful waiting" wherever the prospect of difficult labor is present, particularly in the presence of advanced active disease, especially in the presence of pneumothorax and cavitation. However section in itself is a hazard both as to mortality and morbidity as has been repeatedly proved statistically, and we believe is not indicated simply because the prospective mother has pulmonary tuberculosis.

Brevity of time allotted for the papers in this symposium precludes extensive discussion of the controversial question as to whether surgery upon the tubercular shall be done in the general hospital or in the sanatorium. After a not inconsiderable experience in surgery upon the tubercular and with a moderate familiarity with operation upon pulmonary processes per se, in both sanatoria and hospitals, it has become our conviction that wherever the equipment is ample and the personnel both ample and competent, there is much to be said in favor of the surgical department of the sanatorium. We take a middle ground believing that tuberculosis sanatoria should be properly equipped and manned for surgery, also that the pulmonary patient should not be denied the privileges of general hospitals.

OPERATIVE SURGERY IN THE PULMONARY TUBERCULAR*

BY FRANK H WASHBURN, M D †

WHILE the fundamental principles of surgery are unvarying wherever applied, surgical procedure may properly be modified by dyscrinism, systemic infections and specific diseases that are apart from conditions for which operation may be indicated. Thyroid disease, diabetes, hypertension, toxemia resulting from urinary obstruction, etc., each call for special modifications of procedure in preoperative preparation, anesthesia, technique, and after-care. This is equally true of tuberculosis. Pulmonary tuberculosis is variant not only because it is tuberculosis, but because of involvement of the respiratory system.

In diagnosis, in the subject of active advanced disease, we may find a clouding of the picture. This may be particularly true in cases of acute and subacute infections. We have learned to discount the occasional absence of marked leukocytosis and abdominal rigidity in acute peritoneal cavity disease. Sometimes pain and tenderness appear less than in the average patient similarly afflicted, when keen observation only can appreciate the acuteness of onset, in one carrying the toxic manifestations of pulmonary tuberculosis. The differentiation of acute appendicitis and other infections involving the peritoneum, and tubercular invasions or metas-

tases, may present a difficult diagnostic problem. Here the knowledge of the previous blood picture, always available in the sanatorium patient, is a distinct aid.

Preparation should be meticulously careful in the presence of active disease, and measures should be taken toward avoidance of psychic shock. This becomes easier when operation is to be performed in the sanatorium, but if the patient has been moved to another institution, to new surroundings and among different and strange personnel, care ought to be exercised in the suggestions of initial contact. Morale, so important to the end-results in operative surgery, is particularly so in this field. The toxic patient is infected readily making scrupulous preparation of the skin important.

Selective anesthesia we consider especially important. Could an anesthetic be chosen that would produce complete analgesia and at the same time prevent the effects of traumatism from reaching the cells of the central nervous system, if it would not contribute to surgical shock or would tend to prevent it, if it would not diminish or abolish the coughing or swallowing reflexes, or irritate the bronchial mucosa, and if its effect upon the vital organs, as the liver, kidneys, and heart, were not injurious, the task would be simple. This we cannot do, for ideal anesthetics are yet to be discovered.

Local infiltration with ample amounts of dilute procaine solutions, whenever practical, is safest and most desirable. Regional anal-

†Washburn Frank H.—Thoracic Surgeon Worcester County Sanatorium. For record and address of author see "This Week's Issue" page 1034

and injecting lipiodol. A few weeks after this was taken the patient became quite ill and remained so for about ten days.

Fig. 3 This picture was taken some time afterward a matter of about three weeks. There is the root of a tooth to be seen here, but it was mistaken for lipiodol as there are small amounts still scattered about the lobe.

The patient left the sanatorium against advice and later entered a general hospital where an x ray was taken.

FIG 4

Fig 4 This shows the root of a tooth very plainly. Little if any lipiodol remains in the lobe. The patient was operated on and died. Autopsy proved the shadow to be the root of a tooth. This case shows how obscure a foreign body can be and our assumption is that when this patient had his acute illness described a few moments ago the root of the tooth migrated from the abscess cavity to another portion of the lobe. Careful study of the first picture taken on admission to the sanatorium shows no evidence of any shadow where it was later seen.

CASE II

Female, aged 22. This patient was in bed for two and one-half years treated for tuberculosis. The sputum was never positive, hemoptysis many times averaged once a month. Plain picture showed a shadow which did not look like tuberculosis.

FIG 5.

Fig 5 Bronchiectatic areas after injection of lipiodol.

FIG 6

Fig 6 After removing granulation tissue of the branch bronchial openings much pus was aspirated and lipiodol injected. An abscess cavity seen with a fluid level. Material from this area showed no tubercle bacilli in direct smear culture, or inoculated guinea pigs. The patient had fourteen bronchoscopies over a period of eight months and daily postural drainage. Cough and expectoration ceased. Gained in weight and strength, discharged clinically well. Returned about one and one-half years later still feeling well and free from symptoms and entered the Rutland State Sanatorium Training School for Nurses.

These two cases, I believe, illustrate how more knowledge can be obtained by bronchoscopic instillations of lipiodol than injecting lipiodol supraglottically. In both of these cases the abscess would have been missed had the granulations and debris not been removed through the bronchoscope before instilling the lipiodol.

CASE III

Male, aged 21. The patient was an invalid for five years before admission to this institution. Much

FIG. 7

BRONCHOSCOPY IN THE SANATORIUM*

BY G ARNOLD RICE, M.D.†

SOME eight or ten years ago at a meeting at this institution various members of the Staff read papers on Pulmonary Tuberculosis. I remember one paper that dwelt quite at length on the importance of taking a careful and complete history and after, among other things demonstrating several cases where patients were sent to this institution with the diagnosis of tuberculosis without positive sputum, it was found that they were suffering from some other disease, not tuberculosis. The paper was summed up by saying that a diagnosis of tuberculosis should be made on all facts obtained by the history, physical examination, x-ray and laboratory findings. At that time the reader of the paper cautioned us that in general the diagnosis could not be made on x-ray examination alone, and x-ray at that time was simply one of the aids in diagnosis. A few years later, at another meeting here, the reader of a paper on the diagnosis of tuberculosis summed up his paper by saying that no chest examination was complete without an x-ray examination, x-ray was apparently becoming of more value. Without question the technique of taking pictures and the ability to interpret them had meantime greatly improved. It has been interesting to note that they have continued to improve, until now, with much better x-ray apparatus, films, etc., many times, the diagnosis can be made, I presume, on x-ray examination alone.

However, there are cases where with careful history, physical examination, laboratory and x-ray study, there still remains a question of exact diagnosis. In many of these cases bronchoscopic examination is of great help, also bronchoscopic treatment is of value in many of the patients who have a chest condition found not to be tuberculosis.

I have some slides which I hope will illustrate how the bronchoscope has been an aid in making the diagnosis, also where it has been an aid in treatment. All of these cases have been carefully studied before being referred for bronchoscopy and just enough will be told about them to illustrate the value of bronchoscopy in diagnosis and treatment.

CASE I

Male aged 34. History of cough of ten years' duration. Plain x-ray picture showed nothing definite.

Fig 1 Bronchiectatic cavities after injecting Ipiodol.

Fig 2 Large abscess after removing many granulations, and pus from the branch bronchial openings.

*Read before the Worcester District Medical Society at the Rutland State Sanatorium in the Symposium on Pulmonary Tuberculosis on October 11, 1933.

†Rice, G. Arnold—Bronchoscopist to Rutland State Sanatorium. For record and address of author see "This Week's Issue" page 1034.

FIG 1

FIG 2

FIG 3

done, curved aspirating tube inserted into the right upper lobe bronchus. Few cc. of pus were aspirated. Direct smear showed numerous tubercle bacilli. Diagnosis of tuberculosis made bronchoscopically.

FIG 11

CASE VII

Female aged 29. This patient was sent here with diagnosis of tuberculosis but with negative sputum.

FIG 12

Fig 12 Plain picture taken. No definite diagnosis could be made from this picture. Bronchoscopy was done. Growth was seen in the right bronchus. Biopsy was done. Pathological report: "Adeno-carcinoma." A bilobectomy was done at the Massachusetts General Hospital one and one-half years ago by Doctor Churchill. The right middle and lower lobes were removed. Patient today is living and well, taking care of two children and leading an active normal life. This shows the value of an early diagnosis.

CASE VIII

Male, aged 42. The patient was sent here with a diagnosis of tuberculosis with the sputum negative.

Fig 13 A plain x ray picture was taken. No definite diagnosis could be made from this picture alone. The staff advised chest tap at one of the conferences. This was done with a resulting dry tap. He was referred for bronchoscopy. At the bronchoscopy a tumor was seen in the right major bronchus. Biopsy was done. The pathological report was as follows: "Epidermoid Carcinoma—Type 2." The patient was referred to the Pondville State Cancer Hospital from

FIG 13.

where a number of weeks later, he was discharged as incurable. A few weeks later he died at home. This shows the result in a late diagnosis.

CASE IX

Female aged 31. She was admitted to this institution December 12, 1931 in poor condition and suffering from a severe attack of asthma.

A plain x ray picture showed nothing definite. December 24, 1931 the staff made a tentative diagnosis of tuberculosis. The patient continued to lose weight and to have asthma. January 15, 1932, she was placed on the danger list and her relatives were notified. She was put on digitalis. A week later bronchoscopy was done. Bronchial lavage with normal salt solution. Relief of asthma was immediate. The patient received five bronchoscopic treatments after which she had no more asthma. Her condition in general continued to improve and she was discharged July 26, 1932, in good condition. Diagnosis: Asthma.

CONCLUSION

I wish to say in conclusion that in cases of hemoptysis not proved to be tuberculosis and cases of unexplained cough, we believe that bronchoscopy should be seriously considered as an aid in diagnosis. Bronchoscopy can be done under local anesthesia, general anesthesia is never necessary, the operation can be done in a few minutes without too great inconvenience to the patient.

cough and expectoration, day and night. He was weak, thin and emaciated, had hemoptysis many times. The sputum was never positive for tuberculosis. Plain picture showed nothing definite.

Fig 7 Bronchiectasis, saccular type, an advanced case.

This patient received eighty-two bronchoscopies over a period of twenty-one months and daily postural drainage. He gained in weight and strength, the gain in weight was twenty-two pounds. He was discharged much improved. At the time he was discharged he stated that he felt perfectly well. He is at the present time self-supporting, leading an active life. He has been an employee of this institution for over a year. He still does postural drainage twice a day, which are the only times he coughs.

CASE IV

Female, aged 20. The patient had pneumonia six months ago. Plain picture showed nothing definite. She had failed to gain in weight and strength, continued to cough and had occasional blood-streaked sputum which showed no tubercle bacilli in the smear.

FIG 8

Fig 8 Comparatively early bronchiectasis. Smear of material direct from the bronchus showed no tuberculosis. Cultures and guinea pig inoculations negative for tuberculosis. She had seven bronchoscopies, weekly and daily postural drainage. The cough and expectoration ceased, she gained in weight and strength, and now weighs more than she ever did in her life.

These two cases show the possibilities of bronchoscopic treatment in the advanced case, and in the comparatively early case, how quickly and effectively bronchoscopic treatment can aid in clinical recovery.

CASE V

Female, aged 7.

Fig 9 This picture was shown by courtesy of Doctor Davidson of Worcester, Massachusetts. The patient was taken to Doctor Davidson's office for examination and to determine the advisability of tonsillectomy. The child was thin, pale and below par physically, and had practically no cough. Doctor Davidson found that a roentgenologist in Boston had taken a picture nine months previously. He wrote to the roentgenologist whose report apparent-

ly showed that the same shadow existed nine months before Doctor Davidson made a tentative diagnosis of atelectasis of the right middle lobe. He referred the patient for bronchoscopic examination. Bronchoscopy was done and 15 cc of thick, frank pus was aspirated from the right middle lobe bronchus. Direct smear showed organisms usually found in lung abscess, no tubercle bacilli. A guinea pig was inoculated.

FIG 9

FIG 10

Fig 10 This picture was taken fourteen days after bronchoscopy. It shows the middle lobe clearing. The guinea pig, five weeks after inoculation, was killed and found to have tuberculosis. This is a case of tuberculosis diagnosed with the aid of the bronchoscope.

CASE VI

Male, aged 49.

Fig 11 This picture was shown by courtesy of Doctor Davidson. The patient was a wanderer. He saw nineteen physicians but no diagnosis was made. He was in a general hospital for two months, and left against advice. He had a harsh, non-productive cough, steady loss of weight and strength. He was sent to me by a nurse for bronchoscopy. I referred him to Doctor Davidson for x-ray and advice as to need of bronchoscopy. He was returned to me by Doctor Davidson with tentative diagnoses: 1—Tuberculosis, 2—Large lung abscess. Bronchoscopy was

CHEST SURGERY

Chest surgery is not incompatible with bilateral pneumothorax. Of the 13 cases in the house, three had one intrapleural pneumolysis, two had two pneumolyses operations, and one had three pneumolyses operations performed. The pneumolyses operations were performed by Dr. Frank H. Washburn of Holden. Four cases had a phrenicectomy.

The proportion of the bilateral pneumothorax

to the unilateral form in this sanatorium is about ten per cent. We have here at the present time, 125 cases of artificial pneumothorax, and as mentioned before, 13 are bilateral cases.

EVOLUTION OF PNEUMOTHORAX THERAPY*

BY ARMAND LAROUCHE, M.D.†

THE following is not an attempt to give a complete history of pneumothorax therapy but is a short discussion of a few important points which may be of interest.

In this country, only four years after the original report of Forlanini, the first physician to use this therapy and to urge the medical profession to do so, was John B. Murphy of Chicago who reported five cases in 1898. He later declared that he knew nothing of Forlanini's work at the time. His pupil Lemke¹ reported the treatment of 53 cases by a similar method at a meeting of the American Medical Association in 1901, but his paper was practically ignored, and his premature death was one of the causes of the delay in the acceptance of the treatment by the medical profession in this country. It was not until ten years later that it was used to a certain extent by Harris, Mary Lapham, Robinson, Balboni and Floyd.

In this institution, pneumothorax was introduced in August, 1911. At that time it was looked upon as an experiment, and for experimental purposes was tried out in a large number of cases in the different stages of pulmonary tuberculosis. In 1914, the results were reported as follows: 74 cases had been treated and 23 or 31 per cent had been benefited while 51 or 69 per cent had received no benefit at all.

Alley² wrote in 1919, "those results were considered more or less doubtful and consequently during the last three years (1915-1918) we have given the course of nitrogen gas treatment to but 21 patients, our results however have been much more gratifying and successful. Sixty-six per cent were improved. All the cases had followed the strictest routine as regards fresh air, rest, regulated diet and exercise for several months previous to the gas treatment and still had failed to improve."

The above statement gives a good idea of the type of patient which was given the treatment

at that time not only here but throughout the United States and Europe. With the exception of a few workers in different countries, such as Rist in France, Brauer in Germany, Begg in the United States, and their followers, the majority believed with Kuhn that "pneumothorax treatment was only a last resort for severe and hopeless cases."

These ideas prevailed for several years and were apparently due to lack of scientific control in the selection of cases and to ignorance of the transformations in the chest while the treatment was given. It was only when x-rays were better known, and more liberally used, that the confusion decreased and the value of the treatment was generally recognized.

In this sanatorium, the number of patients treated by pneumothorax began to increase in the early nineteen-twenties. The progress was rather slow at first but was quite rapid during the last four or five years as indicated below:

1928	54 cases treated by pneumothorax 770 x rays taken
1929	117 cases treated by pneumothorax 1074 x rays taken
1930	138 cases treated by pneumothorax 1605 x rays taken
1931	178 cases treated by pneumothorax 1581 x rays taken
1932	194 cases treated by pneumothorax 2180 x rays taken

In the annual report for the year 1925, it is noted that 152 fluoroscopic examinations were done during the year, at the present time we are doing that number every week. I have included these figures to emphasize the extreme importance of the use of the x-rays in the diagnosis and treatment of pulmonary tuberculosis.

During the year 1932, the average number of patients treated by pneumothorax was about 125, or 33 per cent of the total number of patients in the sanatorium, including those who had been started in the previous years and were still under treatment here. The average number of patients treated by pneumothorax in New England at that time was about five per cent.

*Read before the Worcester District Medical Society at the Rutland State Sanatorium, in the Symposium on Pulmonary Tuberculosis on October 11, 1933.

BILATERAL PNEUMOTHORAX*

BY GABRIEL NADEAU, M.D.†

HISTORY

THE first mention of bilateral pneumothorax for the treatment of pulmonary tuberculosis was made in Rome in 1912 at the International Congress for Tuberculosis. In 1928, two excellent studies on the subject were published—one by De Castiglione, the other by Terrasse. In this country, Dr. Geer was one of the first to use it with success. He made a preliminary report of his experience with that form of treatment in 1923¹. It was first used in this institution by Dr. Jacob Kaminsky, who reported on two cases in 1931².

In this country, symmetrical pneumothorax or bilateral pneumothorax was still a debatable procedure until a few years ago, and it has been used to some extent only during the past three or four years. One of the reasons for so little use was the teachings of the physiologists. We read for instance, in the *Treatise of Physiology* of Landois, that "bilateral simultaneous pneumothorax is always fatal."³

CLASSIFICATION

Symmetrical pneumothorax can be divided into two types

- 1—the simultaneous type
- 2—the alternate type

In the simultaneous type, the two lungs are submitted to collapse at the same time. In the alternate type, the opposite lung is collapsed only after the other side has reexpanded.

INDICATIONS

- 1—Early bilateral lesions in young people
- 2—The breaking down of one lung after the opposite lung has been collapsed
- 3—To correct a marked displacement of the mediastinum due to unilateral pneumothorax. In that case only a small marginal collapse is necessary.

CONTRA-INDICATIONS

- 1—Poor general condition. The symmetrical pneumothorax is quite a strain on the patient, and only subjects in good general condition can be expected to improve under it.
- 2—Complications: tuberculous laryngitis, tuberculous enteritis or any other form of active extrapulmonary tuberculosis are contra-indications.
- 3—Acute progressive lesions on both sides.
- 4—Old fibrous lesions.

*Read before the Worcester District Medical Society at the Rutland State Sanatorium in the Symposium on Pulmonary Tuberculosis on October 11, 1933.

†Nadeau, Gabriel—Senior Physician, Rutland State Sanatorium. For record and address of author see "This Week's Issue" page 1034.

TECHNIQUE

- 1—The technique of insufflation is the same as for unilateral pneumothorax.
- 2—It requires closer observation, however, and frequent fluoroscopy, so as not to push the collapse too far and make the patient dyspneic.
- 3—There should be an interval of a few days between the refill of both lungs, although in my service I have a few times refilled a patient on both sides in one sitting without any discomfort.
- 4—A selective collapse should be obtained if possible. It is more important to strive toward the obtaining of a selective collapse in bilateral pneumothorax than in unilateral pneumothorax, because the patient should be left some lung surface with which to breathe. The collapse of the lungs, however, can be pushed surprisingly far. It has been demonstrated that a patient can be comfortable with only a tenth of his lung area left.

PLEURAL COMPLICATIONS

The pleural complications, like the formation of fluid or the perforation of the lung, are not more frequent in the bilateral than in the unilateral form, but they are of more serious consequence. An effusion filling the pleural cavity on one side, and a collapse on the other, will make the patient extremely ill.

REPORT OF CASES

In this institution, we have been using bilateral pneumothorax since 1929. We have had 26 cases up to the present time. Twenty-four were of the simultaneous type, and 2 were of the alternate type. Thirteen were moderately advanced cases and 13 were far advanced cases.

From 1929 to 1931, the staff was a little reluctant to use this form of treatment on early cases. During that period, seven cases were started. They were almost terminal cases, and pneumothorax was done only as a last resort. Four of these had complications, such as tuberculous laryngitis and tuberculous enteritis. After a year or so, the treatment had to be discontinued on five of them because the progress of the disease could not be checked. These five are dead. The other two are living and doing well. Of the remaining 21 cases, seven have been discharged and are doing well. Thirteen are still here under treatment, and are also doing well. The sputum is now negative and has decreased to a scanty amount in 16 of these cases. It has remained positive in five of them. During 1932 and 1933, we have collapsed more ideal cases.

results obtained with it more than justify its use in the numerous cases submitted to it, even if there are occasional complications following the procedure. It is another factor which is largely responsible for the increase in the number of patients treated successfully by pneumothorax. To illustrate this statement, I shall briefly review the work done here on patients admitted in 1932 with regard to pneumothorax treatment.

393 patients were admitted during the year, classified as follows—

- 44 minimal
- 155 moderately advanced
- 159 far advanced
- 7 childhood type
- 3 carcinoma
- 6 bronchiectasis
- 17 unclassified

Of the 358 cases of pulmonary tuberculosis, 145 cases or 40 per cent were considered suitable for pneumothorax therapy. Of this group of 145 cases, 5 or 14 per cent, refused the treatment, in 38 or 26 per cent, there was no free pleural space, in 42 or 29.7 per cent, the pneumothorax was considered effective, and in 60 or 41 per cent, the pneumothorax was consid-

ered ineffective. In this group of 60 ineffective cases, the pneumothorax was discontinued or lost in 17 cases, pneumolysis was attempted in 43 and was considered successful in 33 and unsuccessful in 10 cases. Of the last 10, phrenicectomy was performed in 5 cases and pneumothorax continued, and thoracoplasty was performed in 2 cases. Consequently, instead of having only 42 cases, or 29 per cent of the 145 cases treated effectively by pneumothorax as would have happened a few years ago, we had 80 cases or 55 per cent.

I think that our results justify to say the least, the increase in the number of patients treated by collapse therapy, and we see no reason why these forms of treatment should not be continued and applied to a greater number of patients.

VACCINATION FOR PSITTACOSIS

In the Delta Omega lecture at the Yale Medical School on April 27 Dr Thomas M. Rivers of the Rockefeller Institute for Medical Research proclaimed his belief in the potency of vaccination against psittacosis.

He reported that seven laboratory workers at the Rockefeller Institute had been given this vaccine.

SUMMARY OF MORTALITY FROM AUTOMOBILE ACCIDENTS

NUMBER OF DEATHS APRIL 17, 1932 TO APRIL 14 1934, FROM AUTOMOBILE ACCIDENTS

The Bureau of the Census announces that during the four weeks ending April 14 1934 86 large cities in the United States reported 616 deaths from automobile accidents. This number (616) compares with 513 deaths during the four weeks ending April 15 1933. Most of these deaths were the result of accidents which occurred within the corporate limits of the city although some accidents occurred outside the city limits.

For comparison the number of deaths due to automobile accidents within city limits is desirable. Such figures are available for the four week period ending April 14 1934 and for the corresponding

four week period of 1933 for all of the 86 cities the four week figure in 1934 being 503 as contrasted with 421 for the corresponding four weeks in 1933.

Considering by four week periods since January 1930, total deaths from automobile accidents whether within the city limits or outside the lowest total (513) appears for the four week period ending April 15 1933 and the highest (577) for the four week period ending January 23 1932.

MORTALITY RATES

Telegraphic returns from 86 cities with a total population of thirty seven millions for the week ending April 21 indicate a mortality rate of 12.2 as against a rate of 11.0 for the corresponding week of last year. The highest rate (18.9) appears for St. Louis Mo. and the lowest (6.8) for Yonkers N. Y. The highest infant mortality rate (14.0) appears for New Orleans La. and the lowest for Duluth Minn., Evansville Ind. Grand Rapids Mich., Long Beach Calif., Schenectady N. Y., Somerville, Mass. and Tacoma, Wash. which reported no infant mortality.

The annual rate for 86 cities is 12.6 for the sixteen weeks of 1934 as against a rate of 12.1 for the corresponding period of the previous year—*Bureau of the Census*

A survey was made that same year by Hawes³ who obtained the opinion of thirty to forty leading men in tuberculosis work in this country, including California, New York, the Mid-West and New England, concerning the number of cases out of a given one hundred that should at least be granted the opportunity of having some form of collapse therapy, such as pneumothorax, phrenicectomy or thoracoplasty. The figures varied from 10 per cent to 50 per cent. To mention a few names: Dr Henry D Chadwick, who had 1500 patients under his supervision in Detroit, reported that 57 per cent of them were receiving some form of collapse therapy, Dr Willard B Soper of New Haven gave approximately 60 per cent, Dr James A Miller of New York gave 30 per cent, and so on.

The factor which contributed the most to bring about the definite establishment and general recognition of pneumothorax therapy is, as I have said before, undoubtedly the development of the x-ray which enabled the clinician to make a more judicious choice of cases, to develop a rational technique and to devise methods of increasing the efficiency of the treatment.

Artificial pneumothorax at the present time is the treatment considered for favorable cases and is not recommended for terminal cases as in the past. Of course there is still a great divergence of opinion with regard to the type of case which should or should not be collapsed. "This is due to the differences in the conception of various workers concerning the clinical pathologic states of the diseased lung", according to Dr Edgar Mayer. However, most of the phthisiologists agree that the unilateral case showing caseation, with or without cavity formation, should be submitted to the treatment, but beyond this the agreement ends. Whether the early case, and the bilateral case, should be collapsed is still a debatable question. It is our practice to collapse all early lesions showing clearly on the x-ray. The reason for this is that we see too many young people leaving the sanatorium as quiescent cases, in good general condition, returning sooner or later in a pitiful state. Another reason for so doing is the fact that often small cavities are not visible on the x-ray until after the lung has been partially collapsed, and, finally, because 25 per cent of moderately-advanced and far-advanced cases have no free pleural space. We also collapse readily one lung when the lesion in the contralateral lung is localized and shows signs of fibrosis. Another type of bilateral lesion which we do not hesitate to collapse is the so-called "cross-fire infection" with a cavity in the upper half of one lung and an exudative lesion in the base of the other lung.

The best results are anticipated in cases with lesions localized and showing little or no fibrosis, as cavities with thick firm walls are often only

displaced, or partly collapsed, especially if the mediastinum is mobile.

With reference to technique, Murphy in 1898 advised the introduction of gas into the pleural cavity until the patient was frankly dyspneic, and at least between 2000 and 3000 cubic centimeters for the first dose. He also advocated a very short period of treatment, such as only one dose of gas in certain cases. In 1916, Fishberg⁴ wrote that he himself did not inject more than 300 cubic centimeters for the first dose but that he used as much as 600 for the second and 1200 cubic centimeters for the third dose. He also stated that many workers did not hesitate to introduce two to three times as much, and that some even attempted to secure a complete collapse of the lung during the first operation. In the early nineteen-twenties 1000 to 1500 cubic centimeters introduced every three weeks was still the practice in many places. To start a case now, it is generally accepted that small doses of air, frequently repeated, are much safer and give far better results. It is our practice not to use more than 200 to 300 cubic centimeters of air for the first dose and to repeat it at least twice a week for a while. It is seldom that we give more than 500 cubic centimeters at any one time.

Unfortunately, it is not always possible to induce pneumothorax when it seems indicated, and adhesions often prevent it from being effective when it has been induced. In 1924 Matson⁵ reported

In 600 cases, 120 or 20 per cent had no free pleural space.

In 245 cases, or 40.8 per cent, the collapse attained was only partial.

In 235 cases, or 31.2 per cent only, was a satisfactory pneumothorax induced.

Only a very few did not seem to have adhesions.

For those with no free pleural space, nothing can be done of course so far as pneumothorax is concerned, and up to a few years ago for those with only a partial and ineffective collapse, the operator had only the choice of trying to stretch the adhesions with high positive pressure, which is a very dangerous procedure, or giving up the pneumothorax entirely, and hoping for the best.

Since 1927 (at least in this part of the country, since these procedures had been practiced in Europe for several years) phrenicectomy and pneumolysis have been life savers for a good proportion of those cases.

Phrenicectomy is now used to improve the collapse in connection with pneumothorax at least in this institution only when pneumolysis has failed, and for diaphragmatic adhesions especially, it is still of great help in relieving the pressure and allowing the lung to be further collapsed. It also has the advantage of lessening the dangers of positive pressure.

Pneumolysis is now considered an indispensable adjunct to artificial pneumothorax and the

results obtained with it more than justify its use in the numerous cases submitted to it, even if there are occasional complications following the procedure. It is another factor which is largely responsible for the increase in the number of patients treated successfully by pneumothorax. To illustrate this statement, I shall briefly review the work done here on patients admitted in 1932 with regard to pneumothorax treatment.

393 patients were admitted during the year, classified as follows—

- 44 minimal
- 155 moderately advanced
- 159 far advanced
- 7 childhood type
- 3 carcinoma
- 6 bronchiectasis
- 17 unclassified

Of the 358 cases of pulmonary tuberculosis, 145 cases or 40 per cent were considered suitable for pneumothorax therapy. Of this group of 145 cases, 5 or 14 per cent, refused the treatment, in 38 or 26 per cent, there was no free pleural space, in 42 or 29.7 per cent, the pneumothorax was considered effective, and in 60 or 41 per cent, the pneumothorax was consid-

ered ineffective. In this group of 60 ineffective cases, the pneumothorax was discontinued or lost in 17 cases, pneumolysis was attempted in 43 and was considered successful in 33 and unsuccessful in 10 cases. Of the last 10, phrenicectomy was performed in 5 cases and pneumothorax continued, and thoracoplasty was performed in 2 cases. Consequently, instead of having only 42 cases, or 29 per cent of the 145 cases treated effectively by pneumothorax, as would have happened a few years ago, we had 80 cases or 55 per cent.

I think that our results justify to say the least, the increase in the number of patients treated by collapse therapy, and we see no reason why these forms of treatment should not be continued and applied to a greater number of patients.

VACCINATION FOR PSITTACOSIS

In the Delta Omega lecture at the Yale Medical School on April 27 Dr Thomas M. Rivers of the Rockefeller Institute for Medical Research proclaimed his belief in the potency of vaccination against psittacosis.

He reported that seven laboratory workers at the Rockefeller Institute had been given this vaccine.

SUMMARY OF MORTALITY FROM AUTOMOBILE ACCIDENTS

NUMBER OF DEATHS APRIL 17 1932 TO APRIL 14 1934, FROM AUTOMOBILE ACCIDENTS

The Bureau of the Census announces that during the four weeks ending April 14 1934 86 large cities in the United States reported 616 deaths from automobile accidents. This number (616) compares with 513 deaths during the four weeks ending April 15 1933. Most of these deaths were the result of accidents which occurred within the corporate limits of the city although some accidents occurred outside the city limits.

For comparison the number of deaths due to automobile accidents within city limits is desirable. Such figures are available for the four week period ending April 14 1934, and for the corresponding

four week period of 1933 for all of the 86 cities the four week figure in 1934 being 503 as contrasted with 421 for the corresponding four weeks in 1933.

Considering by four week periods since January 1930 total deaths from automobile accidents whether within the city limits or outside the lowest total (513) appears for the four week period ending April 15 1933 and the highest (877) for the four week period ending January 23, 1932.

MORTALITY RATES

Telegraphic returns from 86 cities with a total population of thirty seven millions for the week ending April 21 indicate a mortality rate of 12.2 as against a rate of 11.0 for the corresponding week of last year. The highest rate (18.9) appears for St. Louis Mo., and the lowest (6.8) for Yonkers N. Y. The highest infant mortality rate (14.0) appears for New Orleans La. and the lowest for Duluth Minn., Evansville Ind. Grand Rapids Mich. Long Beach Calif. Schenectady, N. Y. Somerville, Mass. and Tacoma Wash., which reported no infant mortality.

The annual rate for 86 cities is 12.6 for the six teen weeks of 1934, as against a rate of 12.1 for the corresponding period of the previous year—*Bureau of the Census*

VERMONT STATE MEDICAL SOCIETY

THYROID DISEASES*

BY FRANK H. LAHEY, M.D.†

I WOULD like to discuss with you some of the more recent developments in thyroid surgery and keep away as much as possible from the more common aspects of thyroid disease and so I will perhaps in a more or less haphazard manner, speak of several subjects relating to thyroid states

I first wish to speak of exophthalmic goitre in children. When we first began to deal with exophthalmic goitre or hyperthyroidism in young children for instance at the age of three or three and a half, we were quite timid about the condition because we had not had a background of experience from which to draw and because of the reaction of such young children, particularly as relates to the high degrees of tachycardia in this disease. We all know how easily young children react to any toxic influence and how easy it is for marked tachycardia and high temperatures to result from any intoxication. Our first experiences with hyperthyroidism impressed us very seriously since children of three, four and five with hyperthyroidism were able to show such tremendous degrees of tachycardia and temperature reactions to the disease. At the beginning of our experience we were opposed to operating on these children because of this apparently dangerous reaction but we have learned now from a large background of experience that hyperthyroidism even in very young children, with few exceptions, is very similar to hyperthyroidism in the adult. We know that intense hyperthyroidism in children is perhaps a little more dangerous from a surgical point of view than intense hyperthyroidism in a young adult, but the clinical course of the disease, the reaction and the postoperative results following subtotal thyroidectomy are almost exactly parallel with those following surgical procedures for this disease in adults.

The two exceptions as relates to hyperthyroidism in very young children as compared with the disease in adults are the following: first, the matter of severe postoperative reactions about which we have already spoken. Because of the excessive reactions which can occur in children, thus making it impossible to differentiate true toxicity reaction and the reaction which the very young individual is capable of, it becomes necessary, we believe, in

very severe cases to divide the operation into two stages. We, therefore, feel that in severe hyperthyroidism in young children, if there is the slightest doubt about the condition as to whether the reaction is evidence of true toxicity or of age, it is better to be on the safe side and do the operation in two stages. For this reason, we do a much higher percentage of two-stage operations in young children with severe hyperthyroidism than in adults.

Next, we know that if one removes too much thyroid in an adult, it can be replaced very satisfactorily by the administration of thyroid extract. In children, however, one must realize that the thyroid gland is not only essential for the maintenance of metabolism but also necessary during the course of their development. For this reason, we believe that it is wise to take extreme precaution to be sure that too much thyroid tissue is not removed at the operation and to be certain that minus degrees of metabolism are not produced. We, therefore, believe that in doing subtotal thyroidectomies in children, it is wise to leave larger remnants of thyroid than would be left in a similar case in an adult.

As the result of our experience with a number of these cases, we now feel that the indications for surgery, even in very young children, as young as three years of age, in hyperthyroidism are exactly similar to the situation with adults and the results are equally good.

I want to present to you also one of the dangers relating to exophthalmic goitre which has not been particularly stressed in many of the discussions of this disease and that is, the danger to the eyes. Anyone having a patient with marked exophthalmos must remember that that patient is only a step removed from being totally blind. We have seen six eyes in this disease lost from extreme exophthalmos.

If one has a patient with extreme exophthalmos, this can go on to such a degree that lid pressure produces an edema of the conjunctivae with a wrinkling and molding of the conjunctivae. When one realizes that the conjunctivae receives its nourishment by osmosis and not by direct blood supply, it is easy to understand how readily erosion and slough can occur in this structure as the result of the edema, which causes the piling up and the lid pressure. Once an ulceration has taken place in this edematous and wrinkled conjunctiva, infection of the eyeball eventually requiring enucleation is but a step in advance of the operation.

*Read before the Vermont State Medical Society at its Annual Meeting in Barre October 5 and 6 1933.

If one has a patient with extreme exophthalmos, this can go on to such a degree that lid pressure produces an edema of the conjunctivae with a wrinkling and molding of the conjunctivae. When one realizes that the conjunctiva receives its nourishment by osmosis and not by direct blood supply, it is easy to understand how readily erosion and slough can occur in this structure as the result of the edema, which causes the piling up and the lid pressure. Once an ulceration has taken place in this edematous and wrinkled conjunctiva, infection of the eyeball eventually requiring enucleation is but a step in advance of the operation.

*Read before the Vermont State Medical Society at its Annual Meeting in Barre October 5 and 6 1933

†Lahey, Frank H.—Director of Surgery, The Lahey Clinic. For record and address of author see "This Week's Issue" page 1034

Furthermore, anyone who operates on patients with marked exophthalmos should realize how easy it is to traumatize the eye, produce erosion of the cornea, infection and serious eye infection.

These patients are often taken to the operating room deeply narcotized by preoperative drugging. Unless their prominent eyes are protected, these stuporous patients may unconsciously drag the sleeve of the nightgown across their prominent conjunctiva, produce an erosion, infection and, as already stated, serious eye infection. It is essential also that anesthetists realize the danger of injury to exophthalmic eyes during operation and that these eyes should be protected with vaseline and gutta percha against injury during the anesthesia for thyroid operations.

There is another peculiar type of troublesome exophthalmos that up to recently has been but little understood and that is the postoperative exophthalmos which occurs in the presence of minus degrees of metabolism following successful subtotal thyroidectomy as relates to the relief of symptoms in certain cases of hyperthyroidism.

We have occasionally seen cases as have other surgeons dealing extensively with hyperthyroidism in which subtotal thyroidectomy was successfully done, an excellent result obtained as to relief of symptoms, but instead of the exophthalmos subsiding, it has become progressively more marked and this has gone on even in the presence of marked minus degrees of basal metabolism.

Likewise we have seen such a situation occur in the form of unilateral exophthalmos in a patient operated upon by subtotal thyroidectomy elsewhere with the production of minus metabolism and relief of symptoms but progressive increase in prominence of a single eye.

This type of exophthalmos, occurring as it does in the absence of symptoms of hyperthyroidism and in the presence of a minus metabolism, has always been difficult to understand and there was no satisfactory explanation for it until recently, following the investigation of Dr Howard Naffziger of San Francisco.

Dr Naffziger has demonstrated that the cause of exophthalmos in these cases with minus metabolism is due to a myxomatous infiltration of the ocular muscles producing swelling of these muscles to such an extent that they fill the orbital sockets and push the eyes forward. For this condition, he has developed an operative procedure whereby the bony roof of the orbit is removed, thus producing greater room for the large ocular muscles and so, decompression of the orbital sockets and recession of the prominent eyes.

We have turned three cases of this type over to Dr Gilbert Horrax of our Clinic for this operative procedure, because of his interest in brain surgery.

A bony flap of skull is turned down on either side of the frontal lobe. The frontal lobes on both sides are lifted up and the entire bony roof of the orbit is rongeured away. The fibrous ring of Zinn, which produces constriction due to the swelling at the apex of the orbit is severed, thus relieving a vascular back pressure on the orbital contents. This has resulted in immediate recession of the eye, improvement in the exophthalmos and will be a valuable and useful operation in this hitherto intractable condition.

Another atypical state of hyperthyroidism about which we have written a good deal, is the hyperthyroidism occurring in old people.

One sees two types of hyperthyroidism in older people. Not infrequently when hyperthyroidism occurs in elderly people, there is the typical picture of activated hyperthyroidism as seen in younger individuals. On the other hand, there is a condition which we have termed "apathetic hyperthyroidism" in which many of the striking signs of activation associated with hyperthyroidism in younger individuals are absent.

I am particularly anxious to discuss this aspect of hyperthyroidism because it is so lacking in the striking clinical features of the disease and is, I believe, so often overlooked and undiagnosed.

One should realize that in elderly individuals, hyperthyroidism of this atypical variety may exist in the entire absence of any eye signs, even stare, and entirely without any enlargement of the gland. The gland, however, in this type of hyperthyroidism is usually firm and somewhat nodular as though filled with small pebbles. One should realize that in this apathetic type of hyperthyroidism, contrary to the type of facies seen in activated hyperthyroidism, the features are in complete repose and there is even the appearance of apathy which has caused us to distinguish this condition by the term, "apathetic hyperthyroidism." The forceful pounding apex beat which is so characteristic of activated hyperthyroidism is often entirely absent in apathetic hyperthyroidism, the hyperthyroidism occurring in the aged. The character of the pulse which in activated hyperthyroidism is often so snapping and toxic in character, is frequently not striking in apathetic hyperthyroidism. The skin which in activated hyperthyroidism is hot, moist and flushed, in apathetic hyperthyroidism is often cool, pigmented and wrinkled. The basal metabolism which in activated hyperthyroidism is often strikingly elevated, is in apathetic hyperthyroidism often only moderately elevated twenty-five thirty or thirty-five. There is, as a rule, with apathetic hyperthyroidism a progressive and considerable weight loss which we have stated because the period of time over which it extends is often not appreciated by the patient and frequently not by the examiner.

One should realize that these patients with

apathetic hyperthyroidism who are not activated and so do not present the striking danger signals of activated hyperthyroidism, nevertheless present great possibilities for an operative fatality. While they seem quite safe, it is always possible for them, following a subtotal thyroidectomy, to demonstrate unusual postoperative reactions.

I feel particularly impelled to speak of the postoperative reactions with apathetic hyperthyroidism because they are so different from the postoperative reactions with activated hyperthyroidism. These patients with apathetic hyperthyroidism may go downstairs from the operating room following too much thyroid surgery and instead of becoming delirious with rising pulse rates and marked activation, become stuporous, drowsy, apathetic and finally die in coma. Death with apathetic hyperthyroidism is entirely different from the postoperative deaths in activated hyperthyroidism.

One should always have in mind the possibility of apathetic hyperthyroidism in any patient with marked myasthenia, with moderate but definite and persistent degrees of tachycardia, with pigmented skin and with unexplained weight loss.

So strongly do we feel about the dangers of apathetic hyperthyroidism, that when we feel that any patient has real apathetic hyperthyroidism, we unhesitatingly divide the operation into two stages.

The end results following subtotal thyroidectomy for apathetic hyperthyroidism are quite as satisfactory as with activated hyperthyroidism.

Another somewhat unusual thyroid state is that of intrathoracic goitre. We have now operated upon 1,086 intrathoracic goitres of which 745 or 68 per cent extended nearly to the arch of the aorta in the mediastinum and 341 or 32 per cent extended to or below the level of the arch of the aorta, in the mediastinum.

We feel very strongly that any patient who is having any signs of mechanical respiratory obstruction should have his superior mediastinum x-rayed as to the possibility of an intrathoracic goitre.

We likewise feel from our large experience with goitre, now amounting to between twelve and thirteen thousand goitre operations, that any patient with an adenomatous goitre may have an unsuspected intrathoracic goitre. For that reason, all patients with adenomatous goitres should have x-rays of the mediastinum by which a flattening or deviation of the trachea can be demonstrated and intrathoracic extensions visualized.

We have repeatedly made the mistake of assuming that because the patient had a prominent adenomatous lobe on one side, it was unnecessary to do a mediastinal x-ray. This has resulted several times in our demonstrating in-

trathoracic goitres on the opposite lobe which were entirely unsuspected at the time of the original examination.

We feel strongly, therefore, that when patients have any of the signs that indicate the possibility of an intrathoracic goitre, respiratory difficulty, the presence of an adenomatous goitre or dilated superficial thoracic chest veins, they should always have an x-ray of the superior mediastinum.

No matter how deep intrathoracic goitres are, practically all of them can be removed. The mortality in the very deep intrathoracic goitres will be a little higher than in the average extrathoracic goitre but not materially so. The mortality from January, 1930 to 1933 in the intrathoracic goitres extending nearly to the arch of the aorta was 14 per cent, in those extending to or below the arch of the aorta, it was 25 per cent.

Intrathoracic goitre should not occur. Any patient with a goitre which is tending to become low in location should have it examined each year. If there is a tendency for the lower lobes to extend downward into the chest they should be removed before this extension occurs.

Malignancy of the thyroid gland, in our experience is but little understood by many men. It occurs almost entirely as degeneration of a previously existing benign adenoma or adenomata. We know of no clinical method whereby one can determine that a benign adenoma is or is not malignant. There is a time in all benign adenomata which become malignant, at which the malignancy starts but this fact is not clinically demonstrable at this period. Since practically all malignancy of the thyroid does originate in an adenoma which is originally benign, we feel strongly that all discrete fetal or embryonal adenomata—and these are largely the discrete adenomata—should be removed because of the danger of malignancy in them.

It has been demonstrated by Dr Howard M Clute in this Clinic that malignancy of the thyroid can be divided roughly into four groups. There is a group in which vessel ingrowth, that is, penetration of the adenomatous tissue through the vascular intima of a blood vessel, can be demonstrated. These, while not frankly malignant, are potentially malignant.

The next group is the papillary adenomatous type of malignancy, a type of carcinoma which is extremely radiosensitive. We have had some excellent results in these cases with x-ray therapy.

The next group are the adenocarcinomas in which there is a tendency for local recurrences, but practically all of which ultimately die. Finally, there is the fourth group in which are found most of the malignant cases, the small round cell carcinomas and the giant cell carcinomas which

metastasize locally and distantly and practically all of which cases also result fatally

We feel so pessimistic about the results with x-ray, radium or surgery in malignancy of the thyroid that we feel strongly that the salvation of patients with carcinoma of the thyroid is the removal of the adenomata in which the disease arises before malignant degeneration has occurred

We, therefore, definitely feel that it is wrong for doctors to tell patients with these discrete adenomata that they should not have them cared for until they trouble them, because when they trouble them, as a rule, it is too late to successfully remove them

I should like to speak to you about another condition concerning which we have repeatedly written, but one which occurs only occasionally in any average physician's experience unless he is dealing particularly with thyroid states in considerable numbers, that is the matter of acute hyperthyroidism or thyroid crises. One must realize that when a patient has hyperthyroidism, he is in a state of hypercombustion, that this hypercombustion can and is frequently combated by the patient by means of increased intake of water and food (fluid and fuel). On the other hand, if the hyperthyroidism (hypercombustion) becomes sufficiently intense, the patient will be unable to take in enough fluid and fuel to counteract the effect of this excessive burning-process. When this occurs, and the patient is unable by fuel and fluid intake to counterbalance this hypercombustion, he or she then begins to burn themselves. This then produces a state of acute hyperthyroidism or what we have termed a thyroid crisis.

We know that there are certain early indications attending a thyroid crisis and that if they can be recognized, measures can be undertaken which will successfully, in most instances, combat this excessive effect of hypercombustion.

There are certain conditions which tend to bring about this state of acute hyperthyroidism or thyroid crises one of the most common of which is infection. When a patient with hyperthyroidism acquires in addition an acute infection such as follicular tonsillitis, an alveolar abscess, an acute appendicitis or any other similar state, the hyperthyroidism is immediately intensified and this intensification can go on to the degree where delirium, vomiting and diarrhea occur—the states which characterize thyroid crises. When, for any reason, vomiting complicates the state of fairly acute hyperthyroidism, factors are then immediately present for the production of a serious thyroid crisis.

If a patient is unable to take in fluids or fuel, the elevated metabolism results in excessive combustion which brings about autocombustion, the patient consuming his own glycogen reserve in his liver. This produces further intoxication and undesirable symptoms, further intensification of the hyperthyroidism and eventually,

unless successfully combated, a fatality. Likewise, if patients with hyperthyroidism begin to have a diarrhea, they lose fuel and fluids so rapidly that the state of autocombustion and thyroid crisis may quickly appear.

It is desirable that patients should not be permitted to get into these advanced stages of intoxication with acute hyperthyroidism. For that reason, the onset of such a state should be recognized early and immediate measures undertaken to combat such a situation.

When we have been able to employ the measures to be spoken of, early in the onset of the thyroid crises we have been able to get most of these patients out of the crises successfully and safely.

The measures to be employed in established and impending thyroid crises are fluids, glucose, iodine, hypnotics and narcotics. When patients show signs of impending hyperthyroidism a Hendon indwelling intravenous needle should be tied in the long saphenous vein above the ankle. By means of this indwelling needle, we have been able to give these patients constantly for twenty-four hours intravenous salt solution drip at the rate of forty to sixty drops per minute. This has permitted us also to administer in these cases continuous intravenous glucose solution up to five, six and seven hundred grams in twenty-four hours. The amount of glucose solution which must be administered is dependent on the height of combustion and whether it is spilled over into the urine. One should employ five per cent glucose solution and not ten, since ten per cent in our experience produces thrombosis and occlusion of the vein.

When we first had to deal with these patients with acute thyroid states associated with vomiting and diarrhea, we were at a loss how to administer iodine to them but we have now learned by its repeated employment that it is possible to give iodine intravenously mixed with the salt solution. We, therefore, introduce fifty minims of Lugol's solution per day in the salt solution, giving it intravenously with the salt and glucose solution.

It is necessary not infrequently, because of the activation in these cases, to employ large doses of morphia and patients with hyperthyroidism will tolerate morphia much better than other cases. Sodium amytal and other hypnotics have also been of value in quieting these cases.

With the continuous administration of fluids and fuel in the form of intravenous salt solution and glucose, the effects of hypercombustion can be offset, these patients can be kept out of crises and in many instances be relieved of crises when they have progressed into them so that the advancing intensity of intoxication can be checked.

Once these patients have merged from crises, contrary to the teaching which used to be in

vogue concerning such thyroid states, that is, that it was unwise to operate on patients close to crises, we have put these patients on high carbohydrate diets, large fluid intake and at the end of two to three weeks, after their rescue from the crises, have instituted a first-stage right subtotal hemithyroidectomy. We have then sent them home for six weeks, at the end of which time they have returned for subtotal thyroidectomy on the remaining lobe.

We feel very strongly that when a patient is relieved of a thyroid crisis, unless something is done in the way of removal of thyroid tissue to check the advance of the disease, he may again go into a crisis and it will not be so easy the next time to rescue him from it. For that reason, we believe from our experience that it is wise to institute a first-stage subtotal right thyroidectomy soon after the patient has been removed from his crisis as a precaution against a return of the crisis.

This is an extremely important state and since it occurs only occasionally in everyone's experience, I believe it is important that family physicians be prepared to handle such emergency states by the methods described above, since if this is not done many of these patients in acute crises will die under the ordinary, less aggressive methods of treatment.

I think I can best close my general remarks on this subject with a discussion of what the end results are and what the mortality rates are in these cases. Dr H. M. Clute and Dr J. R. Veil of this Clinic have reported a five-year follow-up study on 97 cases of exophthalmic goitre every one of whom was seen, examined and had a basal metabolism here at the Clinic five or more years after his operation. Of these, 82 patients are perfectly well, requiring no further operation, seven are well with reoperation and removal of more thyroid tissue, three are well with the constant administration of a small amount of iodine and three have myxedema. These are dependable and, I believe, quite satisfactory end result figures in such a serious state.

As stated above, we have now performed twelve thousand, two hundred and forty-six thyroid operations with a mortality in the whole group of 0.73 per cent.

The mortality in the patients with primary hyperthyroidism from 1926 to 1933 was

Total Cases	Total Operations	Total Deaths	Case Mortality %	Operative Mortality %
3,422	4,543	21	0.61	0.48

The mortality in the patients with toxic adenoma for these same years was

Total Cases	Total Operations	Total Deaths	Case Mortality %	Operative Mortality %
876	1,032	16	1.8	1.5

One can see from these figures that we have been able to maintain a very low mortality rate in true Graves' disease, exophthalmic goitre or primary hyperthyroidism. I am anxious, however, to point out that the mortality in toxic adenoma will always be a little higher than that of Graves' disease. This is not in my opinion due to the fact that hyperthyroidism associated with toxic adenoma is any more serious in itself but is due to the fact that toxic adenomata occur in more elderly individuals and, therefore, the operation is associated with more generalized damage such as cardiac, liver and kidney lesions.

In conclusion, I would like to say that thyroid surgery is not dangerous surgery when it is undertaken in organized groups. When, however, it is done as casual surgery, such as the surgery of hernia, fibroid, appendicitis and so forth and without organization for its management, the mortality will undoubtedly be high. The preparation of the cases, the type of anesthesia employed, the technical complications and the postoperative care are extremely important points, I believe, in keeping the mortality low in this group of cases and as demonstrated in the follow-up figures. I know of no operation in surgery in which relief is more striking and the end results more satisfactory.

MISCELLANY

VERMONT DEPARTMENT OF PUBLIC HEALTH

MARCH, 1934

Communicable diseases reported to this department during the month are as follows: chicken pox 88, diphtheria 4, measles 308, mumps 24, scarlet fever 68, typhoid fever 2, undulant fever 2, whooping cough 227 and tuberculosis 15.

The Laboratory of Hygiene made a total of 1,628 examinations in March, classified in the following manner:

Examinations for diphtheria bacilli	122
" " Widal Reaction of typhoid fever	31
" " undulant fever	25
" " gonococci in pus	141
" " tubercle bacilli	199
" " syphilis	504
" of water, chemical and bacteriological	41
" " water, bacteriological	210
" " milk, market	170
" " milk, submitted for chemical only	7
" " milk, submitted for microscopical only	95
" " milk, submitted by the Department of Agriculture	1
" " foods	10

Examinations for the courts (autopsies) ———	0
“ the courts (miscellaneous) ———	5
“ of animal heads for evidence	
of rabies ———	2
miscellaneous ———	60
Autopsies to complete death returns ———	3

Twenty cases of gonorrhea and twenty cases of syphilis were reported to the Division of Communicable Diseases. Four hundred and ninety Wassermann outfits and 380 gonorrheal slides were distributed by this division.

Sixty-five patients have been visited in March by the nurses of the Poliomyelitis After Care Division; eight doctors have been visited and seven social calls made. One patient was admitted to the Massachusetts General Hospital and one patient discharged from this hospital. One patient each has been discharged from the Children's Hospital and the Audubon Hospital in Boston. Fifteen pieces of

apparatus have been fitted, four pieces of apparatus repaired or altered and seventeen orthopedic corrections made to shoes. Sales made by the Vocational Worker amounted to \$16.41.

The State Advisory Nurse's time has been devoted to carrying on the CWA project for nurses. Eight hundred and fifty-seven pieces of literature and 102 notifications of births were sent out in March.

RECENT DEATH

ROGERS — VERN MOORE ROGERS, M.D., died September 18, 1933. He was born in Ashland, New Hampshire, January 25, 1867, and was graduated from the Medical College at the University of Vermont in 1897. Dr. Rogers was located in Quechee for a few years, practiced in Middlebury for about three years, after which he returned to Quechee where he practiced until his health failed in 1930.

AN EXTRACT FROM A LETTER OF SIR WILLIAM OSLER*

The letter closed with this charitable comment on the Semitic invasion of Berlin:

"The modern 'hep hep hep' shrieked in Berlin for some years past has by no means died out and to judge from the tone of several of the papers devoted to the Jewish question there are not wanting some who would gladly revert to the plan adopted on the Nile some thousands of years ago for solving the Malthusian problem of Semitic increase. Doubtless there were then as now, noisy agitators—prototypes of the Parson Stocker—who clamoured for the hard laws which ultimately prevailed and for the taskmasters whose example so many Gentile generations have willingly followed of demanding where they safely could bricks without straw of their Israelitish brethren. Should another Moses arise and preach a Semitic exodus from Germany and should he prevail, they would leave the land impoverished far more than was ancient Egypt by the loss of the 'Jewels of gold and jewels of silver' of which the people were 'spoiled.' To say nothing of the material wealth—enough to buy Palestine over and over again from the Turk—there is not a profession which would not suffer the serious loss of

many of its most brilliant ornaments and in none more so than in our own. I hope to be able to get the data with reference to the exact number of professors and docents of Hebrew extraction in the German Medical Faculties. The number is very great, and of those I know their positions have been won by hard and honourable work, but I fear that, as I hear has already been the case, the present agitation will help to make the attainment of university professorships additionally difficult. One cannot but notice here, in any assembly of doctors, the strong Semitic element at the local societies and at the German Congress of Physicians it was particularly noticeable, and the same holds good in any collection of students. All honour to them!"

A STUDY OF FAMILIES WITH CONGENITALLY MALFORMED MEMBERS

The Gynecean Hospital Institute of Gynecologic Research of the University of Pennsylvania is conducting an intensive study of families into which congenitally malformed individuals have been born.

Special interest centers in families in which malformations have appeared in two or more children. Physicians who have knowledge of any such families are urged to communicate with Dr. Douglas P. Murphy, Gynecean Hospital Institute, University of Pennsylvania, Philadelphia, Pa.

*This letter written by Sir William Osler while visiting in Germany in 1884 appears in *The Life of Sir William Osler* by Harvey Cushing, Volume I 214 1906.

PREVENTION OF LITIGATION REQUIRES EARLY AND THOROUGH EXAMINATION AND A CORRECT DIAGNOSIS

BY HENRY F STOLL, M D *

THERE is no question but that the rank and file of the medical profession look askance at medico-legal cases and there is ample justification for this feeling. Any doctor who has been baited, browbeaten and held up to ridicule by some clever attorney who demanded a "yes" or "no" answer to a preposterous question, has no desire to repeat the experience.

Moreover the conflicting testimony of so-called experts who specialize in the litigation field, sometimes makes one question the integrity of the witnesses. Nevertheless, the growth of accident insurance and the advent of compensation laws place an added responsibility upon all of us whether we like it or not.

Since the earliest times, the desire to get something for nothing has been universal but it has been more flagrant and unashamed since litigation appeared as an easy way to this end. Yet I am convinced that the majority of the litigants, who on careful investigation are found to have no justification for their claims, are honest in their contention.

It is not my intent to discuss the great variety of injuries and diseases that are attributable to industry, but it may be of interest and perhaps helpful to review some of the diagnostic problems that arose in a few cases. They illustrate that litigation with its attendant worry and expense, might often be avoided if the physician first consulted would take sufficient time to ascertain and record all the facts and thoroughly examine his patient.

CASE 1 H. G. L. aged 67, while driving his automobile had a head on collision with another car. The impact turned his car completely around though it did not upset. He was not conscious of being injured as he got out of the car unaided and went into his house nearby to phone for the sheriff. He worked a day or two after the accident, but almost none since. The natural inference that he had not worked as the result of the accident was found to be incorrect, the real reason being that he had finished the job he was working on and could not get another.

About a month after the accident, he had a drawing sensation in the region of his heart. Two or three months later he lost his appetite and developed nausea, and about six months after the accident, and five months before I saw him he became very weak and lost about 40 lbs in weight. He had never been constipated prior to seven months ago. I examined him eleven months after the accident at which time he honestly, and quite naturally, attributed his condition to the collision. He was alert, emotionally unstable and emaciated. Pulse 80, blood pressure 155/85, tenderness was quite marked over the epigastrium especially toward the right, where a sense of fullness was suggested.

I suspected that he had a carcinoma of the stomach, but a rectal examination revealed a hard cartilaginous mass just inside the anal sphincter. X-ray suggested a small duodenal ulcer and a filling defect of the rectosigmoidal juncture, thought to be caused by a neoplasm.

Comment Notwithstanding the fact that his symptoms were chiefly confined to the epigastric region, there was one symptom of great significance, especially in an elderly individual, that I at first overlooked. For the past several months he had been constipated. In every patient past middle life who notes a change in his bowel habit, either the development of diarrhea or constipation, a careful search for neoplasm of the large bowel should be made.

A strongly positive Wassermann reaction complicated the picture. Whether the rectal lesion was malignant or syphilitic, with secondary involvement of the liver, could not be determined, though the former seemed probable. There could be no causal connection between the development of the duodenal ulcer (if he had one) and the accident six months before.

Irrespective of the complaints or the social status of the patient, subsequent embarrassment is often avoided if a rectal examination and Wassermann test are routinely made.

CASE 2 T. K. aged 65, a buffer and grinder for 40 years could no longer work because of pain across his chest, lack of 'pep,' loss of weight and a cough of six months duration. Twice tuberculosis had been diagnosed and both times he was sent to a sanatorium, but soon discharged as having no active tuberculosis. Pneumoconiosis was then considered and he claimed compensation, asserting that his symptoms were due to the 40 years of grinding. A rather natural claim in view of his occupation. Further questioning, however, revealed that the pain across the front of the chest was gripping in character especially if he hurried. He also stated that he thought if he could get rid of the gripping he would also get rid of the cough which was especially bothersome at night.

Physical and roentgenological examination of the lungs revealed neither recent tuberculosis nor pneumoconiosis. The examination of the heart was likewise negative but, from the clinical picture, the diagnosis of arteriosclerotic heart disease was justified.

Comment Too little time had been spent in eliciting the patient's symptoms. Cough is often one of the earliest symptoms of a failing myocardium. "A grinder for 40 years" has an ominous sound but we have found that the use of emery and carborundum wheels when equipped with adequate exhaust systems, does not cause pneumoconiosis, whereas with the large silica wheel,—the so called "wet grinding" now rarely used—extensive involvement is frequent.

In all industrial cases, the actual working con-

*Stoll, Henry F.—Visiting Physician, Hartford Hospital.

page 1034

ditions should be investigated. For instance, the roentgenograms of a molder who had tuberculosis strongly suggested a co existing pneumoconiosis. In addition to making the molds with moist sand and pouring the molten metal he also cleaned the castings. This would hardly seem to incriminate the occupation but on visiting the foundry, I learned that he sprinkled so-called "parting compound" on the mold before pouring as this made the separation easier. This preparation is almost pure silica. But of more importance was the method used in cleaning castings.

For the most part they were large pieces,—manhole covers, etc. They were placed on a low bench and the operator "scrubbed" them with a wire brush bending over so that his face was a couple of feet from the casting. The adherent sand had a high silica content and this must have been increased by the particles of "parting compound" that adhered to the metal. Obviously the amount inhaled must have been considerable.

CASE 3 C J aged 46 a night watchman for two and a half years in a typewriter factory could no longer work because of weakness. Benzol poisoning was alleged as one of the ingredients used in what is known as the japanning process. The manufactured articles, after being covered with the enameling solution were baked in kilns at high temperature. He had lost weight (40 lbs.), had numbness in fingers and legs, diarrhea and occasionally bright blood with the stool. It had been observed that his skin was yellow.

In addition to ringing the boxes and inspecting the clocks, he made regular inspections of the kilns. Varying amounts of gas and smoke were always evident about the kilns and this was occasionally so strong that his eyes would water and he would have to put his head out of the window to get his breath.

On examination a lemon yellow tint to the skin was evident. There was marked weakness in the legs so that he could not stand unaided. The tongue was very red and, along the edge seemed denuded of epithelium. Both knee reflexes and the right ankle reflex were absent.

An international authority on industrial diseases testified that the man was suffering from benzol poisoning and a claim for complete permanent disability was made yet in reality there was little to support this claim save the fact that he had a severe anemia and had passed a little bright blood with stool a few times. He had had no petechiae or real hemorrhages which are always present in benzol poisoning. The blood picture was definitely not that of aplastic anemia, such as occurs in benzol poisoning, but was typical of primary anemia. (Hb 40 RBC 2.3 WBC 5500. Red cells varied much in size hyperchromia was present and some specimens showed blasts.) Free HCL was not found in either of two examinations of gastric contents. moreover combined system disease so common in primary anemia, does not occur in benzol poisoning.

Comment The inhalation of gases and fumes is frequently the basis of a claim for disability, yet the most lethal gas (CO) is without odor while some with a disagreeable odor, as for example, banana oil, is harmless. The intermittent exposure to benzol fumes in the case of the

night watchman was much less than that experienced by the regular workmen in the plant and no case of benzol poisoning had developed during many years of operation.

CASE 4 W W aged 57, claimed compensation because of disability due to typhus fever. When admitted to the hospital he complained of pain in the region of the right shoulder accompanied by fever of three weeks duration. Tenderness was marked and motion was exceedingly painful. He gave a history of having strained his shoulder over six months before while loading railroad ties onto a freight car. The pain gradually subsided but, on the seventh day after admission to the hospital his temperature rose to 103.4° for one day. For a couple of days he was slightly drowsy. The spinal fluid pressure was normal there were ten cells and a slight globulin reaction. Wassermann was negative, colloidal gold, a slight rise in middle zone.

Greatly to everyone's surprise, a positive Weil-Felix reaction was obtained on the blood. Up to this time no one had considered the question of typhus fever. Further questioning developed the fact that while working at his trade as a carpenter, about a month before admission to the hospital, and just prior to the development of his symptoms, he was repairing an old house and opened up a large nest of bats that flew about his head. He reached in and with his bare hand removed a large amount of "bat wool." He was not conscious of being bitten by a bat, nor did he recall any insect bites. That night he had a sudden sharp pain in the back of his neck. He indicated the spinous process of the seventh cervical vertebra. The pain in the shoulder had been present since that time a period of about four weeks.

European typhus is due to the *Rickettsia prowazeki* and the vector is the human body louse. Examination of the patient, however, did not reveal any lice. Though the bats are reputed to harbor a variety of mites and parasitic flies they do not, so far as is known harbor human lice. In this country however, typhus fever is not transmitted by the body louse but by rats and conveyed to human beings by the rat flea. Unsuccessful attempts were made to capture rats in the vicinity of the old house where the man had worked.

X-ray examination of the right shoulder and spine showed evidence of chronic arthritic changes in the right acromioclavicular joint and advanced hypertrophic changes in the dorsal spine. The urine at all times showed a few pus cells and at the time of the second rise of temperature pus cells were reported as being present in clumps.

Comment Clinically, he had a typical acute, periarticular inflammatory process of the shoulder, probably with a complicating bursitis and pyelitis. The mental symptoms suggested a mild encephalitis.

It is quite likely that his work started up an old quiescent arthritis of the shoulder. In the effort to prove that the man was "bit by the louse that fell from the bat, that flew from the house that Jack built," the actual condition, that was probably compensable, was lost sight of and as a consequence, the case was thrown out of court. Valuable as laboratory tests are, one can sometimes be led very far astray unless they are considered in conjunction with the whole clinical picture.

CASE 5 C L., aged 66, sued a hotel proprietor for \$25,000 alleging an attack of ptomaine poisoning with subsequent injury to his heart, as the result of eating food served at the hotel.

The claimant, a retired merchant, spent the winter of 1931-1932 in Florida, returning the first of May. While there he played a great deal of golf and in fact, had been particularly active and in good health. On the morning of May 7, he breakfasted at 7:30 in New York City. He partook of no other food or drink until his luncheon which was eaten in Hartford shortly after three o'clock in company with his wife and two daughters. The question was raised as to the advisability of eating oysters, as it was the month of May. The claimant's luncheon consisted of raw oysters, soup, a piece of chicken with mushroom sauce and asparagus salad. One of the daughters ate the oysters, chicken, ice cream and coffee. His wife and other daughter did not eat the oysters, but the rest of the luncheon was the same.

The entire party was very hungry and the claimant had had nothing to eat for about eight hours. The food, including the oysters, looked to be good and tasted so. While waiting for the waiter to pass the menu for the dessert order, the claimant began to feel ill. He had a vague sickening feeling in the abdomen. He decided to eat no dessert and thought he would feel better if he got out into the air, so without saying anything to the family, arose and walked out of the dining room, through the lobby and out to his car standing near by. The chauffeur noticed nothing unusual in his appearance. He got his overcoat for him, helped him into it and the claimant got into the back seat unaided. While he was walking out from the dining room, however, he felt very weak and had to "push himself" and he was somewhat unsteady. Almost immediately after getting into the car, the chauffeur heard a peculiar noise and turned around to see him vomiting profusely and for a moment he appeared to be unconscious. His breath came in short gasps and his face appeared to be swollen. The unconsciousness was only momentary.

The other members of the family came out after finishing their luncheon, in perhaps fifteen to twenty minutes. He presented a ghastly color and refusing their advice to summon a physician, immediately started for his home in Springfield. On the way he was nauseated, but did not vomit. He got out of the car at his home unaided, walked upstairs without assistance, to his room and dropped upon the bed. He did not know anything thereafter until he regained consciousness several hours later when he saw a nurse, two doctors and a priest in the room. He remained in bed for four weeks because of weakness. At no time did he suffer from pain, vomiting or diarrhea. His recovery was despaired of when he was first seen. He was very slow to regain his strength and has had to limit his activities greatly since then because of shortness of breath and of discomfort in the left side of the chest on exertion.

At the time of my examination, seven months later, the heart was apparently enlarged slightly to the left, the sounds were faint and there was a soft systolic murmur following the first sound. Pulse 92, blood pressure 150/75. The examination was otherwise negative.

Comment The claimant was very hungry at the time of the luncheon and ate heartily and within fifteen to twenty minutes after beginning the meal he began to feel ill, "a great weakness", he called it. He suffered from no pain, walked a considerable distance, became momen-

tarily unconscious, vomited profusely but after the initial vomiting there were no gastrointestinal symptoms whatsoever, except for an attempt to vomit on the journey to Springfield.

Food poisoning of any sort could be absolutely ruled out as the time between the ingestion of food and development of symptoms was too short.

During the past few years it has become more and more evident that individuals, especially past middle life, apparently in the best of health who are seized with so-called acute indigestion, usually have an occlusion of a cardiac vessel. This has repeatedly been proved at autopsy and while there is usually pain, which is almost always intense, it is not uncommon for pain to be entirely absent. An overwhelming sense of weakness, accompanied by sweating, appears to be the pain equivalent in this case.

The attacks of coronary occlusion occur so frequently in individuals who are feeling perfectly well, just after or while eating a hearty meal, that it would seem as though there was some connection between the ingestion of food and the attack. One may assume that the coronary circulation is already impaired, due to vascular sclerosis, and that possibly the engorgement of the blood vessels of the gastrointestinal tract, as the result of the ingestion of food, is sufficient to lower the blood pressure in the already sluggish coronary circulation enough to cause thrombosis. The distention of the stomach, with the change in position of the heart, may contribute to this.

When vomiting follows the attack as it often does, it almost invariably brings temporary relief from the pain even though there is no food in the stomach and this naturally suggests the diagnosis of acute indigestion. The relief will usually last only a few moments, but is repeated with each succeeding attack of vomiting. It would seem as if the rise in blood pressure coincident to the strain of vomiting were sufficient to force enough blood through the small collateral vessels to momentarily overcome the muscle anoxemia.

The case here reported was won by the defendant on a point of law, not of fact as to what caused the sickness. The lower court ruled and was sustained by the higher tribunal, that the hotel sells service—not food and consequently does not guarantee its purity.

CONCLUSION The physician first consulted after an alleged injury has a great responsibility. If he fails to get a complete description of all the details that precede as well as follow the incident, if he neglects to examine the patient with meticulous care, if he makes a thoughtless remark or comment, great harm may result. The fear that a serious condition has arisen, the hope that financial security may be achieved, and the months of uncertainty while the wheels of the law slowly revolve, have wrecked many an individual past any possibility of salvage.

ACROMIOCLAVICULAR DISLOCATION AND ITS REPAIR

BY FREDERIC J. COTTON, M.D.,* AND GORDON M. MORRISON, M.D.*

THE understanding of this dislocation, appreciation of its seriousness, and of the various problems offered in the handling of the injury, have not been helped by the confusion between two lesions different enough to be classed entirely apart.

The common lesion, occurring usually from falls on the shoulder, common on the football field for instance, involves nothing beyond tearing of the ligaments directly connecting the clavicle and the acromion.

Sometimes there is a crumpling fracture of the outer end of the clavicle, but not often. There is a little upward displacement of the upper end of the clavicle, usually only a half an inch or so. Unless there is much muscle spasm this displacement is reducible by shoving the arm upward, particularly with the patient on his back.

Treatment with any sling or apparatus to hold the whole arm up beyond the ordinary carrying point, brings about prompt healing of ligaments with displacement nearly enough abolished to leave no measurable disability as a rule.

Rarely it may seem advisable to suture the ligaments or to reeve a fascial strip through the bones across the joint. This lesion is really hardly important.

The other lesion, from like violence but of severer force, involves not only a tearing of the ligaments about the joint, but also of the massive conoid and trapezoid ligaments holding the clavicle to the coracoid process of the scapula. Such a tear may be so complete as to allow a direct displacement of the outer end of the clavicle upward. In two such cases, rather neglected, I have seen such displacement of at least two to three inches. Ordinarily it is less, but very definitely more than in the lesion first described. The bone-end may be replaced but not easily, and is hard to hold. Such an injury is serious. Mere confinement after reduction is entirely inadequate treatment. Even operation at the joint is a waste of time.

Radical operation is the only cure. Various lashings have been used, but to day one would use only fascia. The only reliable treatment is an operation of obvious mechanics, but one I think not often done. The incision runs from the pectoral insertion on the humerus up to and a bit beyond the clavicle, crossing about an inch and a half inside the outer end. This incision opens directly onto the interval between the deltoid and the so-called clavicular portion of the pectoralis major. Here lies the cephalic vein.

Blunt dissection separates the muscles. The vein is carried outward, occasional ties may be needed.

High up in the space the coracoid process presents an obvious hook. From it arise the tendons of origin of the pectoralis minor and the short head of the biceps. Blunt dissection opens up room behind them thereby permitting a circling of the coracoid hook. Directly above this point the clavicle, here broadened out is drilled through but not encircled. It is drilled from above downward, a spatula being held beneath

ACROMIOCLAVICULAR LUXATION

- 1 Acromion.
- 2 Coracoid.
- xxx Torn ends of ligaments on clavicle and on coracoid process
- 3 Conoid ligament with normal attachments
- 4 Trapezoid ligament with normal attachments
- 5 The knotted fascial band through clavicle around coracoid, back of the attachments of origin of the muscles
- 6 Direct suture of torn acromioclavicular ligaments.
- 7 8 and 9 The short head of the biceps the coracobrachialis the lesser pectoral at their origins

it, to guard against any slip. The hole is enlarged to a quarter or even a third of an inch.

The fascia a long and very strong strip is obtained from the fascia lata in the usual way, cleaned, rolled up to a cord, passed down through the clavicle under the coracoid from within outward (behind the tendons so it cannot slip off) brought up and forward, tied in a square knot with the free end lying in front just below the clavicle. The knot is caught with stitches of chromic gut or silk as usual. Next comes the repair of the acromioclavicular ligaments, probably not very important. After this operation, firm sling support is needed for at least six weeks.

As in all surgery with fascial sutures, there is presently some slack, no matter how tight the fascia is drawn, and how firmly knotted. I have done this operation on about six cases. In all that I have done or observed, thus operated on, the results have been mechanically competent and clinically good. And this applies to several cases operated some weeks after injury.

CASE RECORDS of the MASSACHUSETTS GENERAL HOSPITAL

ANTE MORTEM AND POST MORTEM RECORDS AS USED
IN WEEKLY CLINICAL-PATHOLOGIC EXERCISES

EDITED BY RICHARD C CABOT, M.D.
F M PAINTER, A.B., ASSISTANT EDITOR

CASE 20191

PRESENTATION OF CASE

First admission A married American housewife of forty-two entered on the Neurological Service for the first time complaining of headaches of a year's duration

A year before admission she began to suffer from severe frontal headaches which occurred on an average of three times a week. They were not accompanied by nausea or vertigo, but were sufficiently severe to make her lie down. At about the time of their onset her physician noticed a tumor in her abdomen, but did not recommend any treatment for it. At the same time she noticed a lengthening of her menstrual periods from her usual three and a half days to eight days. The headaches became gradually more frequent until they occurred daily. They did not change in character. Five months before her entry to this hospital she awoke one morning with blurred vision and an exceptionally severe headache. She entered another hospital, where three lumbar punctures were done with temporary relief of the headache. X-ray studies were made and abscesses about the teeth found. Six teeth were removed. While in the hospital she had severe earaches, but no operation was done on her ears.

Her family history shows that her father was living and well at seventy-five. Her mother died at sixty-three of cerebral hemorrhage. The patient had been married twenty-one years. Her husband was living and well. She had one son, aged nineteen. She had a single miscarriage at the age of thirty.

She had been told that she had malaria from the age of three to six. She had the usual childhood diseases, and also had diphtheria in childhood. She had been constipated all her life, being accustomed to taking cathartics daily.

Physical examination showed a well nourished, rather pale woman with a moderate upper dorsal kyphosis. The heart measurements were within normal limits. The blood pressure was 124/74. The chest was negative. A firm, hard, smooth, non-movable, slightly tender tumor about the size of a pear was felt in the epigastrium, pulsating up and down but not laterally. On auscultation over it a systolic bruit could be heard. The liver edge was barely

palpable and slightly tender. Pelvic examination showed a tumor the size of a grapefruit which appeared to move with the cervix. Neurologic examination was negative.

She was afebrile. Her pulse averaged 80 and her respirations 20.

Laboratory examination showed a red blood cell count of 4,120,000, a hemoglobin of 55 per cent, a white cell count of 4,600. The urine showed a specific gravity of 1.012 with no albumin, no sugar, and a negative sediment. The non-protein nitrogen was 24 milligrams. Examination of the colon by barium enema was negative.

A lumbar puncture gave 13 cubic centimeters of clear colorless fluid with an initial pressure of 170. The dynamics were normal. Alcohol and ammonium sulphate tests were negative. Thirty-nine crenated red cells were observed. The Wassermann and colloidal gold were negative.

She was transferred to the Surgical Service, where a dilatation and curettage with an implantation of radium was done under avertin anesthesia. At this time the cervix was found to be smooth and normal in size. The uterus above it was definitely enlarged and somewhat irregular. No masses could be made out in either vault. The cervix dilated easily. The uterine cavity measured four inches in depth. With the curet a localized hump could be made out on the posterior wall. Several smaller nodular irregularities were felt on other portions of the wall. The curettage produced only a small amount of grossly and histologically normal endometrium. Two hundred and thirty-five milligrams of radium were inserted for six and a half hours. Three days later she was discharged with advice to continue under observation with a view to hysterectomy if the bleeding did recur.

History of interval Following her discharge her headaches continued on an average of three days out of every week. The pain was now described as most severe in the occipital rather than the frontal region. There was general relief at the times of the menstrual periods. She took the iron prescribed for her anemia faithfully and adhered to the other dietary requirements advised. Her color improved and she gained thirteen and a half pounds in weight. Her menstrual periods continued in spite of the radium treatment. Until the last one before her reentry, however, the flow was relatively scant in amount. Four days before her reentry she suddenly passed a large amount of bright red blood and numerous clots. The following day this stopped. The day before entry she had another severe hemorrhage, but without further clots.

Second admission, nine months after her previous discharge

Physical examination at this time was unchanged from the preceding entry. On pelvic examination a slight flow of blood from the external os was noted. The fundus was found to extend three fingerbreadths above the symphysis and seemed about the size of a small orange. The vaults were negative except for marked tenderness on the left.

Her hemoglobin on this occasion was 80 per cent. The red cell count was 4,430,000.

Three days after entry operation was done, a supravaginal hysterectomy, bilateral salpingo-oophorectomy and appendectomy. Following the operation she had persistent vomiting for three days. On the fifth day after operation at about midnight she suddenly complained of sharp severe epigastric pain. There were at the time no other symptoms. The pain was relieved by a grain of codein followed by one sixth of a grain of morphine. At seven o'clock the following morning the patient became suddenly dyspneic and cyanotic and collapsed. When seen by the doctor she was lying in bed showing marked air hunger. Cyanosis was extreme. The extremities were somewhat cold. She was rational and talked intelligently. At this time she had no chest pain. The abdomen appeared distended. No peristalsis could be heard. The veins were not distended. The blood pressure and pulse gradually became imperceptible. The patient became comatose and died fifty-five minutes after the onset of the final collapse.

DIFFERENTIAL DIAGNOSIS

DR JAMES C WHITE. On thinking about this patient perhaps the first question to clear up is the matter of these headaches. I should say that they were not typical of migraine. She had blurred vision on only one occasion. The pain shifted from the frontal to the occipital region at the second admission. Could they have been due to any cerebral lesion? I feel that with the negative neurological examination and the relatively normal spinal fluid findings the chances of definite pathology in the brain should be fairly slight. Perhaps the anemia resulting from her uterine bleeding is an adequate explanation of her headaches.

Next we have the problem of the pelvic tumor. I think we must discount the epigastric tumor, because they would have had a chance to feel it at operation, and it was never mentioned except at the first admission on the medical ward. She had, as I gather, an enlarged uterus rather than an ovarian tumor. At the dilatation and curettage they found definite irregularity in the inside of the uterus, in fact a number of irregularities. They found a normal endometrium. If she had had a Shaw type of tumor of the ovary causing bleeding she should have shown hyperplasia of the endometrium. If she had had carcinoma of the uterus they certainly

ought to have been able to find it with the curettage. Every now and then, however, a small area of carcinoma can be overlooked, so that this possibility must still be considered with the subsequent course of this patient.

She was given 1500 millicuries radiation. Of course she was so anemic that they were unwilling to do the more usual type of hysterectomy. I should like to know in connection with radiation in what percentage of cases that dosage should cause cessation of ovarian function. I should like to ask Dr Leland if he feels that this amount of radiation would definitely stop the function of the ovary.

DR GEORGE A LELAND, JR. In a large proportion of the cases, yes, but not in one hundred per cent if you are dealing with ovarian function alone.

DR WHITE. If you said ovarian function could always be counted on to stop after this degree of radiation, then we should have to fall back on malignant tumor as the cause of her continued bleeding. The most usual type of neoplasm would be carcinoma, but this would probably have been discovered on curettage. Occasionally sarcoma will cause bleeding, and sometimes sarcoma is associated with fibroids. I think that is still a possibility to be considered. On the law of chances, however, I should say she had fibroid tumors of the uterus and the radiation did not completely stop ovarian function, that she may have had a partial breaking down of one of the tumors without complete destruction, and that this was causing symptoms at the second admission. If she had had any malignant tumor you would not expect her to gain fifteen pounds, nor would it be likely that her hemoglobin and red cell count should return to almost their normal levels.

Operation was done. The removal of the uterus with both tubes and the appendix would be compatible either with fibroids or malignant tumor, so we cannot tell by that what the surgeon found.

The final question comes down to this: why did she collapse on the fifth day after operation? She had a stormy postoperative course. After radiation and the findings that were described it would be very likely that she developed peritonitis after operation. Her symptoms of collapse however are perfectly typical of pulmonary embolism. She became cyanotic, developed severe dyspnea, and her extremities became cold, as is commonly the case in extreme circulatory failure. These observations are certainly suggestive of pulmonary embolus. The fact that she had no pain in the chest would also be perfectly compatible with this diagnosis.

I should like to ask Dr Boyden about her veins. We are told that the veins were not distended. Does that mean the leg veins or the neck and arm veins?

DR A M BOYDEN. I did not see her at that

time, but the note that appears in the record was that the veins were not distended

DR TRACY B MALLORY I think it is fair to presume it means the neck and arm veins, because statements as to distention of the neck veins and regarding cyanosis appear in every history where there is any question of pulmonary embolus

DR WHITE I think that this is the one vital and essential sign This patient was alive for almost an hour and they had plenty of time to observe it With complete shutting down of circulation in the pulmonary artery and dyspnea you must get distention of the right side of the heart If you fail to detect distention of the large veins in the neck, you cannot logically make a certain diagnosis of pulmonary embolus, even though the other findings are typical You do not often get it in cardiac infarction, but this woman is too young for coronary occlusion The fact that she had abdominal distention and absent peristalsis makes me feel that her death was due to a fulminating peritonitis

CLINICAL DISCUSSION

DR REGINALD H SMITHWICK This patient had multiple fibroids of the uterus and was operated on under general anesthesia While she was receiving the ether she had some sort of circulatory collapse in the etherizing room Her pulse became very rapid and feeble and her blood pressure dropped from about 120 to 70 or 80 There was some question as to whether we should go ahead and do the operation or not She was given a slow intravenous infusion and seemed to improve rapidly, although that fact is rather disconcerting

On opening the peritoneal cavity we found that it contained a large quantity of fresh blood, bright and not clotted On rapid exploration of the pelvis the right tube was found to be distended with clotted blood The appendix was adherent to the right tube and was separated with a little difficulty On quick observation it looked as though she might have had an extrauterine pregnancy, particularly as the radium had never stopped her periods At any rate she was in poor condition A rapid hysterectomy was done, removing both tubes and ovaries and incidentally her appendix, which of course one would not be particularly anxious to do under the circumstances except that being involved with the right tube and ovary it seemed a little wiser to take it out than not Because of her poor condition no attempt was made to remove all the fluid blood and the wound was closed undoubtedly with a large quantity of free blood

Her postoperative course was similar to that which is very frequently seen with ectopic pregnancies where not all of the blood is removed at the time of operation because of the condition of the patient and the fact that you do not

want to handle the intestines too much She had a little more temperature after operation than she should have had, but that subsided, and by the third or fourth day we were no longer concerned about her abdomen

Then the sudden episode happened during the night I did not see her She died at about 7 45 in the morning, very suddenly, apparently having a good deal of pain during the night which was not relieved by the medication, as I understand the story I believe that more emphasis should be placed on difficulty in breathing and cyanosis, which I understand from talking with some who saw her were present from the time of the episode about midnight Also I think Dr White has been misled by the statement that the veins were not distended I did not see her until after she had died and the neck veins were distended very definitely It seemed to me from the reports over the telephone and on looking at her after she had died that she died a perfectly classical and typical death of pulmonary embolism

DR LELAND In listening to the discussion and the description of this case I noted several very interesting points that may well be discussed. I will mention three of them

In the first place the question of radium and fibroids,—what radium may be expected to do and what it was expected to do in this particular case I was on duty at the time this patient was in the neurologic ward I saw the patient in consultation and felt definitely that with a hemoglobin of 55 per cent surgery should not be attempted I do not believe it is justifiable to subject a woman to a hysterectomy, either supravaginal or complete, with a hemoglobin below 60 When the cause of hemorrhage is benign, radium may suffice to obviate that hysterectomy, or failing in that will act as a hemostatic sufficiently to permit the patient to build up the hemoglobin In fibroids of the uterus it is not anticipated that radium will always stop the bleeding In a submucous fibroid it is never expected that radium will stop the bleeding Apparently that was just the situation in this case The surgeon who did the curettage found irregularities in the endometrial canal which were interpreted by him as submucous fibroids

As regards the dose of radium, 1500 millicuries is sufficient in we will say eighty-five per cent of the cases of fibroids at this age to bring about the menopause, but it is not sufficient in ninety-five or ninety-seven per cent, in which a dose of 2500 millicurie hours is required I think men who use the lower dose—and there are justifiable reasons why they do use that lower dose—must bear in mind the necessity of a repetition of that dose

In this particular case, as soon as the submucous fibroids were found an attempt was made

to get the patient into shape for hysterectomy

The second point was this intraperitoneal hemorrhage, which naturally enough was supposed to be due to an extrauterine pregnancy, although the surgeon must have given some thought to the question of pregnancy following the use of radium. The history shows us that no evidence of extrauterine pregnancy was found. I wonder how we can account for that bleeding. We know that the uterus still bled, and we know that radium has a certain stenosing effect upon the uterus. I offer as a possible explanation that a portion of the uterine bleeding came out through the tube instead of through the external os due perhaps to a submucous tumor so placed that a partial atresia of the uterus prevented the bleeding from coming down through the cervical canal.

As regards the final point, the cause of death, certainly the immediate rise in temperature, the vomiting and the evidence of diminution in peristalsis all lead one to suspect peritonitis. On the other hand we have the evidence of the physician in charge that on the third day the condition of the abdomen failed to give any concern. In these cases one must always bear in mind the possibility of phlebitis of the ovarian plexus. Such a phlebitis may occur with or without a local pelvic peritonitis and is not infrequently the cause of death by pulmonary embolus. I am inclined to reconstruct the immediate cause of death in this fashion, that there was a local pelvic peritonitis—it is unusual not to find it with such an amount of bleeding—with free blood present at the time of operation, that there was a phlebitis of the ovarian plexus, and that the final termination was due not to spreading peritonitis but to a pulmonary embolus from that ovarian plexus and phlebitis.

CLINICAL DIAGNOSES

Leiomyoma uteri
Intraperitoneal hemorrhage?
Coronary thrombosis?

ANATOMIC DIAGNOSES

Operative wound supravaginal hysterectomy,
bilateral oophorectomy and salpingec-
tomy, appendectomy
Pulmonary embolism
Hemoperitoneum
Pelvic peritonitis
Double ureter, right

PATHOLOGIC DISCUSSION

DR TRACY B MALLORY The surgical speci-
men which was removed at the hysterectomy
showed an enlarged uterus with multiple sub-
mucous fibroids, as had been suspected from the
time of the first curettage. The tube which was

seen at the time of operation and thought to be
a ruptured ectopic was considerably dilated and
filled with blood. Microscopically this and the
other tube showed a very slight degree of lym-
phocytic infiltration but no very significant
degree of chronic salpingitis, no evidence what-
ever of any decidual reaction and nothing to
suggest placentation or embryo formation, so
that I think we are reasonably safe in ruling
out ectopic gestation.

As Dr Leland suggests a hemorrhage from
the uterus through a patent tube seems reason-
able. According to Sampson's many articles
it is common to find during the menstrual periods
a certain amount of oozing through the tubes
if an exploratory laparotomy is done at that
time, and in the case of very severe uterine
hemorrhage such as this woman had it might be
possible for a very significant amount of blood
to pass through the tube into the pelvis.

There was a small paraovarian cyst.

The autopsy showed a very considerable
amount of blood in the pelvis and there was no
question that this blood was infected because
the pelvic contents had a distinctly foul odor
and were slightly purulent in character. There
was however no generalized peritonitis. The
immediate terminal event was a pulmonary em-
bolism, in all probability from the pelvic veins,
since the iliac and femoral veins were entirely
free. An incidental finding was a double ureter
on the right.

I think Dr White was at a disadvantage
working simply from the record, because that
statement as to the lack of distention of the neck
veins was probably made at an early period of
observation. Very possibly a change was made
and there was no note at any subsequent time.
I agree with Dr Smithwick that after death the
veins were definitely distended, but I believe
that can occur postmortem.

DR WHITE I think we have to go on that—
we simply cannot make a diagnosis of pulmonary
embolism in the case of a patient who lived as
long as she did unless these veins are distended.

DR MALLORY There was some doubt be-
cause the diagnosis sent down from the ward was
coronary thrombosis rather than pulmonary
embolus. So I think the distention was not an
important feature of the case at any rate.

A PHYSICIAN Where was the pulmonary
embolus?

DR MALLORY Lying in the pulmonary artery
just at the bifurcation—a very sizable one.

CASE 20192

PRESENTATION OF CASE

A seventy-six year old unemployed Negro
entered complaining of acute retention of urine
of five days' duration.

For a period of somewhat over a year he had
had mild symptoms of urinary obstruction—

frequency, nocturia, slowness of the stream and some difficulty in starting the stream. He had never noted hematuria or pain. Five days before entry he suddenly developed complete retention, requiring catheterization by his physician. Repeated catheterization was necessary during the subsequent four days. On one occasion this produced slight bleeding.

His past history included an attack of rheumatism thirty years before entry characterized by swollen wrists and ankles. For thirty years he had noted edema of the ankles. Four or five years before entry he had been told that he had heart trouble. For two years he had had slight dyspnea on exertion and had noted occasional dull precordial aching. He had been operated on for a hydrocele. He denied venereal disease.

His wife was dead. He had two children who were living and well. There had been no miscarriages or stillbirths.

No family history could be obtained.

Physical examination showed a well-developed man. The heart was enlarged. A powerful apex impulse could be seen and felt in the sixth interspace two centimeters beyond the mid-clavicular line. Obscuring the first sound there was a long rough systolic murmur which could be heard all over the precordium. In the aortic area a soft short diastolic murmur was heard which was transmitted down both the right and left sides of the sternum. There is no note as to a thrill. The aortic second sound was greater than the pulmonic. The blood pressure was 150/60. The pulse was regular, the rate 60 to 70. The lungs showed a few moist râles at both bases. The abdomen was distended on admission. There was a large area of suprapubic dullness and the bladder could readily be palpated. Rectal examination showed a prostate enlarged to the size of a large orange, smooth, symmetrical, non-tender. There was bilateral pitting edema of both ankles.

The temperature ranged from 98° to 100°, the pulse from 60 to 80, the respirations from 20 to 25.

The only laboratory work recorded is a single urine examination showing a gravity of 1.010 and the slightest possible trace of albumin. The sediment showed occasional white cells and 8 to 10 red cells. The non-protein nitrogen was 38. The Hinton test was negative.

The patient was placed on constant drainage. Two days after entry a bilateral vasectomy was done.

X-ray examination two days later showed both lung fields clear. The outline, position and respiratory movements of the diaphragm were normal. The heart lay rather horizontal in the chest and was considerably increased in the transverse diameter. The curve of the left ventricle was prominent. The apex was blunted. There was marked increase in the supracardiac shadow due to tortuosity and dilatation of the aorta, the tortuosity being regarded as extreme. Plates

of the pelvis showed proliferative changes about the bodies of the vertebrae and also at the points of attachment of several muscle tendons. Several round dense shadows were noted in the pelvis and were regarded as phleboliths. After the dye had been given the kidney pelvis failed to fill completely, but as far as made out were not abnormal. The ureters also appeared normal.

On the morning of the sixth day after entry the patient was up and about feeling very well. He went to the bathroom, where he collapsed suddenly, was found unconscious, and was brought back to his bed. He did not appear cyanotic. The veins were not distended. The pulse was fairly strong, the rate 90. The respirations were irregular. He remained unconscious and died in about five minutes, the respirations continuing for several seconds after the heart had stopped beating.

X-RAY INTERPRETATION

DR AUBREY O HAMPTON. This supracardiac shadow is very wide in the anteroposterior view, but if you rotate the patient the shadow almost disappears. That finding is fairly characteristic of extreme tortuosity of the aorta without much dilatation. It does measure 5 centimeters at the arch and it ought to be 3.5 to 4 centimeters, so that there is probably slight diffuse dilatation without obvious aneurysm.

The heart is of the left ventricular hypertrophy type that we see with aortic valve lesions or hypertension.

That is all, except some pleural reaction.

DIFFERENTIAL DIAGNOSIS

DR WILLIAM B BREED. I will not consider the genito-urinary aspect of this case, but will try to divide this second part of the story into two phases. It is interesting to consider first what the underlying cardiac pathology is and later to consider what was the cause of his sudden death.

There are some interesting statements, for one, the attack of so-called rheumatism at the age of forty-six. Rheumatic fever is not common at that age, and the incidence of heart disease following rheumatic fever at that age is low. He also stated that he had edema of his ankles for twenty-eight years before he began to have other symptoms of cardiac failure. I can not explain that on the basis of cardiac disease. He may have had varicose veins.

The physical examination indicates a very large heart. It shows a long rough systolic murmur obscuring the first sound and heard all over the precordium, also an aortic diastolic murmur. He may have had mild rheumatic heart disease with mitral involvement and aortic regurgitation. We may find that there is some rheumatic pathology, but I should think from the story and the x-ray evidence most of his trouble was arteriosclerotic in origin. It is pos-

sible that if they had focused their attention on the aortic valve they might have found some calcification there by x-ray. So I should say that we shall find chiefly arteriosclerotic heart disease with dilatation of the aortic ring as a background.

What was the cause of his death? I think that cerebral hemorrhage or other process in the head is most unlikely because of the suddenness with which he died. I am not considering that seriously. One is tempted to lay a good deal of emphasis on the possibility of pulmonary infarct, since the attack was postoperative. We are told definitely here again, however, that he did not appear cyanotic, the neck veins were not distended, and he did live for five minutes with a strong pulse and a rate of 90. He may have had a pulmonary embolus, but I am against it.

It is purely a guess as to other possibilities. I think there are two main ones, namely coronary occlusion and dissecting aneurysm of the aorta.

One thing in favor of dissecting aneurysm is the extreme degree of arteriosclerosis with a defect of the aortic valve to the point of giving him aortic regurgitation. It is rather intriguing to make an antemortem diagnosis of dissecting aneurysm. I have never done it. I think it is not done very often. Most cases of dissecting aneurysm have been associated with aortic regurgitation.

If coronary occlusion were severe enough to kill him in five minutes one would not expect to have a fairly strong pulse with a rate of 90 directly after his accident. As I said however, I think it is purely guesswork as to whether he had coronary occlusion or a dissecting aneurysm. Just as a sporting chance I am in favor of dissecting aneurysm.

DR FLETCHER H COLBY: There is not much more to be said about the genito-urinary aspect of this case than Dr Breed has said, except this, that this patient was a colored man of seventy-six. The colored race shows the largest prostates that we see. Sometimes they are huge in size. Uniformly these patients do not do well from operation or even in the preoperative course. There are several reasons for that. The first is of course sepsis. It is extremely common and practically universal in these patients who have been carrying a residual for some time and have been catheterized with a certain amount of trauma. When they come here they are likely to be put on constant drainage either by using catheters in the urethra or by an immediate cystotomy done to drain the bladder suprapubically. The presence of an indwelling catheter always produces a certain amount of infection. Most of these patients are elderly men and are able to take care of that type of infection. The prostate in this patient was described as being the size of an orange. Along with that one expects an engorgement of the periprostatic plexus

of veins. That added to sepsis very often results in a phlebitis of these veins with an extension into the pelvic veins. It is not uncommon at all for such a patient to have pulmonary embolism even though no major operative procedure has been done. I think I remember the cause of death in this case, so it is a little unfair to say that I suspect pulmonary embolism. Certainly the course of events was much more as Dr Breed described it and the death may have been due to coronary occlusion or heart failure of some sort, but it would not be unusual for such a patient as this who is put on constant drainage to have pelvic phlebitis followed by embolism.

A PHYSICIAN: May I ask what type of anesthesia was used in doing the operation?

DR COLBY: The vasectomy was done under local anesthesia.

DR J H MEANS: May I mention a colored man who died suddenly? He was not so old as this patient,—in his early fifties. He had worked for me for a number of years. I never had anything to do with his medical care. Apparently he was in perfect health until one day when he went home saying he did not feel well, he went to the toilet and dropped dead. I was interested in learning from the medical examiner's report that all they could find was arteriosclerotic heart disease and a wet brain. I do not understand why these conditions should kill him, nor do I understand what the relationship was. The situation was something like this one.

DR TRACY B MALLORY: One certainly sees a certain number of anginal cases in which death is nearly instantaneous and in nearly all these cases one fails to find a thrombus in the coronary artery, although there is always narrowing and arteriosclerosis.

DR MEANS: Do you usually find a wet brain?

DR MALLORY: I have not noticed it in two such cases that I have examined.

CLINICAL DIAGNOSES

Obstruction of the prostate
Arteriosclerotic heart disease with aortic regurgitation

ANATOMIC DIAGNOSES

Prostatic hyperplasia
Operative wound, bilateral vasectomy
Pulmonary embolism
Arteriosclerosis, splenic and renal
Cardiac hypertrophy, hypertensive type
Chronic endocarditis, aortic, with calcification
Pulmonary emphysema
Cortical cysts of the kidneys

PATHOLOGIC DISCUSSION

DR MALLORY: The anatomic findings in this

frequency, nocturia, slowness of the stream and some difficulty in starting the stream. He had never noted hematuria or pain. Five days before entry he suddenly developed complete retention, requiring catheterization by his physician. Repeated catheterization was necessary during the subsequent four days. On one occasion this produced slight bleeding.

His past history included an attack of rheumatism thirty years before entry characterized by swollen wrists and ankles. For thirty years he had noted edema of the ankles. Four or five years before entry he had been told that he had heart trouble. For two years he had had slight dyspnea on exertion and had noted occasional dull precordial aching. He had been operated on for a hydrocele. He denied venereal disease.

His wife was dead. He had two children who were living and well. There had been no miscarriages or stillbirths.

No family history could be obtained.

Physical examination showed a well-developed man. The heart was enlarged. A powerful apex impulse could be seen and felt in the sixth interspace two centimeters beyond the mid-clavicular line. THE ANNUAL MEETING

PLANS for the approaching meeting of the Massachusetts Medical Society in Worcester are now nearing completion. The meeting will be held June 4, 5, and 6 in the Hotel Bancroft, and the Chamber of Commerce Hall, which is under the same roof. The detailed program will be published in the May 17th issue of the *Journal*, but certain features of the arrangements are of sufficient general interest to warrant editorial comment.

The Local Committee of Arrangements has prepared clinics in the leading hospitals of the city on Monday morning, and it is hoped that a large number of Fellows will arrive in time to attend them. This Committee has also planned a program of entertainment for the ladies. All Fellows of the Society are cordially invited to bring their wives, and are asked to register for them at the Registration Desk in order that

they may be welcomed by the Ladies' Entertainment Committee. The balcony of the ballroom has been reserved on Tuesday evening for those ladies who may care to hear the distinguished speakers at the Annual Dinner. Arrangements have also been made for all Fellows and their wives who wish to play golf to do so as guests of the Society.

Of recent years there has been an increasing interest in the Scientific and Commercial Exhibits at the Annual Meetings, and an effort has been made this year to secure those especially worthy of attention. All suitable space on the ground floor of the hotel has been reserved for this purpose. The Commercial Exhibits will be in the main dining room, the lobby, and the assembly of the main ballroom. The Scientific Exhibits will occupy the small ballroom, directly behind the main ballroom, and a large part of the mezzanine floor.

It is hoped that Fellows will avail themselves of the opportunity of examining all of these exhibits at some time during the meeting.

WILLIAM HENRY WELCH (1850-1934)

THE death of Dr. Welch, "Popsy" to a legion of endeared friends, brings to an end a life so full so gloriously rich in all those qualities of mind and hand, that his passing, sad as it is, seems but an incident in the career of one who lived through an age of great development in medicine, not a little of which was of his own making. To have seen the very beginnings of modern pathology and bacteriology and to have been privileged to bring these gifts to America at a time when enthusiastic colleagues helped in their development, to have found friends and money to inaugurate a great medical school and later a school of public health and an equally eminent one of the history of medicine, were the gifts from the gods to a worthy son. The genius of Welch flowered under such inspiring and nourishing influences. The results of the meeting of a man, opportunities and the divine inspiration were never better exemplified.

To others will fall the task of depicting his official achievements. Many, moreover, have already paid him just tribute, not perhaps the least those friends who met the world around on his eightieth birthday in 1930 and whose declarations of devotion are ably presented in the memorial volume published by the Milbank Fund. The dedication of the William H. Welch Medical Library, too, brought forth a burst of universal accord to the man whose services to his profession were apotheosized by that building. With all his honors, however, he was essentially a simple man, kindness, courtesy, and thoughtfulness to others enveloped him like a natural cloak. In his presence his interests al-

case were a fairly marked degree of arteriosclerosis and a calcified aortic valve with definite stenosis and undoubtedly some degree of regurgitation. The coronary arteries were in relatively good shape. The immediate cause of death was a pulmonary embolism which I think undoubtedly came from the periprostatic plexus of veins, which has been a very frequent source of pulmonary emboli in our material. We have had at this hospital one fatal case in which the operation was simply the crushing of a bladder stone through a cystoscope, no other operative procedure at all, and the patient died within four or five days with embolus.

A PHYSICIAN The death was sudden, was there no distention and cyanosis because of that?

DR MALLORY I can only say that there is frequently no mention of cyanosis in these case histories.

DR HOWARD B SPRAGUE Were the aortic cusps rigid?

DR MALLORY Not entirely. The calcification was mostly at the base, there was still a little freedom at the margins.

A PHYSICIAN The note was that the aortic second sound was louder than the pulmonic second.

DR MALLORY Yes, that is distinctly unusual, is it not?

DR SPRAGUE Yes.

DR MALLORY The calcification was not so extreme as in many of the cases we have seen here.

DR HAMPTON We have been seeing aortic valve calcification in ordinary films now that we know what to look for, but we could not see it in this case. I am sure that careful fluoroscopy would have revealed the calcification, however.

DR SPRAGUE Is there no evidence that this was a rheumatic process on the aortic valve?

DR MALLORY That is always difficult to tell. We have a rheumatic history, and I have seen a rheumatic history in four or five of these cases of aortic stenosis in elderly people. His mitral valve was absolutely negative. One must assume either that rheumatic fever occurring in an

older age group has a predilection for the aortic rather than the mitral valve or else that it is not rheumatic at all.

A PHYSICIAN Why should the veins become distended?

DR JAMES C WHITE You immediately get right heart failure, you see. Following the damming up of the circulation in the right heart, the neck and arm veins are the first to become distended.

DR COLBY He died pretty quickly.

A PHYSICIAN There were five minutes.

DR WYMAN RICHARDSON May I make a speech, more in connection with the first case than this? I have thought for a long time that pulmonary thrombosis, the thrombosis that leads to embolism, must occur at that time when most factors favor coagulation, and therefore it seems reasonable that this thrombosis may occur during the period of greatest blood stasis. There may be marked blood stasis in the veins during the period of anesthesia and flaccid paralysis because of the fact that the tone of the muscles and the muscular movements do aid venous return, and also at the time of operation, when trauma increases coagulation and when pressure relations are changed in the abdomen. Furthermore, there may be trauma from pressure of instruments. Therefore thrombosis may occur during the period of anesthesia and at the time of operation. It might be true therefore that one might get increased venous circulation by active measures during the period of anesthesia, and thus prevent thrombosis. I have not the brains nor the opportunity to work out this theory. I wonder if anyone else might possibly do something with it.

In regard to this last case, it would seem that sepsis was the important factor.

There have been patients who have died of pulmonary embolism on the operating table before the incision was made.

DR MALLORY One does have to bear in mind always the possibility that thrombosis may have occurred before operation. Probably in these prostatic cases that is actually the situation.

The Massachusetts Medical Society

THE ANNUAL MEETING

PLANS for the approaching meeting of the Massachusetts Medical Society in Worcester are now nearing completion. The meeting will be held June 4, 5, and 6 in the Hotel Bancroft, and the Chamber of Commerce Hall, which is under the same roof. The detailed program will be published in the May 17th issue of the *Journal*, but certain features of the arrangements are of sufficient general interest to warrant editorial comment.

The Local Committee of Arrangements has prepared clinics in the leading hospitals of the city on Monday morning, and it is hoped that a large number of Fellows will arrive in time to attend them. This Committee has also planned a program of entertainment for the ladies. All Fellows of the Society are cordially invited to bring their wives, and are asked to register for them at the Registration Desk in order that

they may be welcomed by the Ladies' Entertainment Committee. The balcony of the ballroom has been reserved on Tuesday evening for those ladies who may care to hear the distinguished speakers at the Annual Dinner. Arrangements have also been made for all Fellows and their wives who wish to play golf to do so as guests of the Society.

Of recent years there has been an increasing interest in the Scientific and Commercial Exhibits at the Annual Meetings, and an effort has been made this year to secure those especially worthy of attention. All suitable space on the ground floor of the hotel has been reserved for this purpose. The Commercial Exhibits will be in the main dining room of the lobby, and the assembly of the main ballroom. The Scientific Exhibits will occupy the small ballroom, directly behind the main ballroom, and a large part of the mezzanine floor.

It is hoped that Fellows will avail themselves of the opportunity of examining all of these exhibits at some time during the meeting.

WILLIAM HENRY WELCH (1850-1934)

THE death of Dr. Welch, "Popsy" to a legion of endeared friends brings to an end a life so full, so gloriously rich in all those qualities of mind and hand, that his passing, sad as it is, seems but an incident in the career of one who lived through an age of great development in medicine, not a little of which was of his own making. To have seen the very beginnings of modern pathology and bacteriology and to have been privileged to bring these gifts to America at a time when enthusiastic colleagues helped in their development to have found friends and money to inaugurate a great medical school and later a school of public health and an equally eminent one of the history of medicine, were the gifts from the gods to a worthy son. The genius of Welch flowered under such inspiring and nourishing influences. The results of the meeting of a man, opportunities, and the divine inspiration were never better exemplified.

To others will fall the task of depicting his official achievements. Many, moreover, have already paid him just tribute, not perhaps the least those friends who met the world around on his eightieth birthday in 1930 and whose declarations of devotion are ably presented in the memorial volume published by the Milbank Fund. The dedication of the William H. Welch Medical Library, too, brought forth a burst of universal accord to the man whose services to his profession were apotheosized by that building. With all his honors, however, he was essentially a simple man, kindness, courtesy, and thoughtfulness to others enveloped him like a natural cloak. In his presence his interests al-

ways seemed your interests and no matter how important the event, perhaps even international in its scope, Welch never forgot his intimate surroundings, nor did he ignore the friendly touch, the pleasant word, the cordial greeting. In these respects he was much like Osler, his companion in the Hopkins days and afterwards.

That his work was broad and sound is beyond question. To him, almost alone, America owes the revivification of medicine. The establishment here of pathology and bacteriology was in itself an achievement of prime importance. The grouping of a few great teachers of medicine at Baltimore in the late eighties and the stimulus he gave to each of them, multiplied a hundredfold by their students, was, without doubt, Welch's greatest contribution. Set at a very high standard, the School might easily have foundered had it not been for the supreme figure at its helm. His influence, in those early days, radiated to every corner of the laboratories and hospital, as it later came to penetrate all aspects of medicine and even the life of every citizen of the United States. As years went by, hardly any important problem in medicine, medical education or public health was decided in this country without his sanction. Few men have had a wider outlook or a more penetrating gaze, for he truly, of all men in recent days, "saw life steadily and saw it whole."

Well does the writer of this note remember some memorable nights on the open rear veranda of 13 Norham Gardens, Oxford, with Osler and Welch talking far into the night. The topic at hand concerned the inclusion or exclusion of certain medical worthies in Osler's *Bibliotheca Prima*, then being assembled for the forthcoming catalogue of Osler's library. The great men in medicine offered, of course, no scope for argument, but when it came to some of the lesser figures, like Conrad Gesner, time passed quickly in contemplation and discussion. Rarely could one man mention a fact regarding an historical figure that the other was not perfectly familiar with. The hungry student who sat by was completely overwhelmed, for two giants in medicine had met and he was within hearing. That was fifteen or more years ago and yet the picture stands forth to-day in the writer's mind with the clearness of an etching.

Other events crowd in upon memory a thoughtful day with Welch in a fifteenth century Cardinal's library in Germany, during the days of the American Army of Occupation, some incidents in an hotel room in London, a few hours at a hospitable home in Switzerland, and glorious days in Baltimore, not by any means least, the fifteenth of February last, when Welch greeted us from his bed, then occupied for over a year, at the Hopkins Hospital. With all these splendid memories, intimate

and perhaps relatively superficial, can one separate the man, his work, and his influence?

AMERICAN COLLEGE OF SURGEONS

Six months hence we are to have the annual meeting of the American College of Surgeons in Boston

This annual convocation is always of interest and importance, not only because it means two or three thousand surgeons in Boston (or wherever it may be) but because it connotes a vast quiet movement, a movement toward better standardized, better controlled, more intelligent work in all the hospitals of the land

The College is but twenty years old, but in its time it has done much

With coöperation of the American Hospital Association it has, very quietly, reorganized standards of hospitals from coast to coast

And this has been as the result simply of a universal "showdown", of a careful systematic evaluation of what we had, and an insistence on what we should have in order to serve the common good, professionally

The first idea of the college was to educate the profession to higher standards

Much has been and is being done in this direction and the coming meeting is planned not only to show work and results, but to reach the public

Just as it presently became evident that we must improve hospitals in order to help surgeons' work, thus necessitating the great hospital campaign, so it has become evident that

to make our work possible on a rising plane we must first educate the profession, directly

Therefore, we have seen the College take up branches of work such as are carried on by the Cancer Committee, The Registry of Bone Sarcoma, The National Fracture Committee, The Committee on Health and Hospitalization, and the Committee on Industrial Surgery

Much good work has been done by these and by their sub committees and regional groups

And the "regional" meetings of the College all over the country have been of rare educational value

Unfortunately, here in New England, possibly because we have thought that we needed this work a little less and have cooperated less actively, these educational enterprises have been less energetic hereabouts and less obvious We have perhaps undervalued the College and its work We can be assured, however, that, the country over the results accomplished by the College have been profoundly important

And now comes a further development In order that we may well serve our public, *the public must be educated*

And in this coming session, for the first time, are to be stressed the meetings on *private health*

Public health, vastly important, has its say What is now to be stressed is the education of John Doe as to what the qualified doctor can do for him, and his

Come to think of it, this is pretty nearly an untouched field, and this year the College is going to enter it, in earnest

There is every indication also that the coming session as a clinical session is in no way likely to fall below the high standard previously set

Organization for the meeting began last October, and not only are the medical schools and the recognized urban hospitals ready to do their full part, but in larger measure than ever before the outlying hospitals are counted on to do their part The amount of clinical instruction offered at these meetings is rather amazing in bulk and scope

All this organization is of course, closely associated with the Central Offices

Director Dr Franklin H Martin
Assistant Director Dr Bowman Crowell.
Hospital Head Dr M McEachern
Business Manager Mr A. D Ballou.

DR. PHANEUF ADDRESSES THE MEDICAL
SOCIETY OF THE COUNTY OF NEW YORK

Dr Louis E Phaneuf addressed the Medical Society of the County of New York on Monday evening April 23, the subject of his address being The Diagnosis and Treatment of Placenta Previa

CORRESPONDENCE

TWO QUESTIONS RESPECTING ARTIFICIAL
INSEMINATION

Editor, *New England Journal of Medicine*

During the past week a quantity of most unfortunate publicity has been given by the lay press to the subject of artificial insemination, under the ridiculous caption of 'test tube babies'. I call this publicity unfortunate, because it is inevitably destined to raise among childless people false hopes which are doomed to disappointment. Since Morris Fishbein has seen fit to mention a published paper of mine in this connection, I have been drawn more or less into the discussion. I should like, therefore to make certain facts clear.

Two distinct questions must be considered. The lay press with its characteristic preference for sensationalism rather than accuracy confuses the two. They are as a matter of fact, entirely separate. The first is the value of artificial insemination simply as a therapeutic measure in sterility. The second is the propriety of artificially introducing semen from an alien donor into the wives of hopelessly sterile husbands or into unmarried women.

The first question is medical and may be definitely answered. If natural intercourse allows the penetration of normal spermatozoa into the uterus then no extra advantage whatsoever is to be gained by artificial insemination, and certainly no mysterious miracle can be wrought by such means. If, however there is hypospadias or impotence or extreme dyspareunia or an obstinate hostility of the endocervical mucus, then artificial insemination may be used to overcome the obstacle. I have found it advisable to employ this method in five cases of sterility out of some 800 cases seen and treated in the past fifteen years.

The second question is basically sociologic, though legal and moral issues are raised by certain polemicists in the present discussion. If an intelligent woman seriously decides that she wants to have a baby by a man other than her lawful husband I should say only that the worthiness of her purpose and the best manner of its accomplishment are matters upon which different opinions may reasonably be held. Dogmatic pronouncements upon such a subject are particularly unconvincing.

SAMUEL R. MEAKER, M.D.

475 Commonwealth Avenue Boston Mass

ANOTHER VIEW OF AN EXPENSIVE DISEASE

Editor *New England Journal of Medicine*

In the *Journal* of April 12 1934 there appeared a letter from Frank H Dunbar M.D., under the heading 'An Expensive Disease'. I should like to make the following comments on that letter.

In the first place Dr Dunbar's figures are misleading if not erroneous. He leaves the impression that but two cases from the town of Mansfield were treated at the Bristol County Hospital in 1933 and that the total hospitalization was 107 days. The fact is that four patients from Mansfield were treated at the Bristol County Hospital in 1933 for a total of 366 hospital days. In his calculations he excluded two patients because they themselves paid a weekly charge of \$9.10 and he failed to mention that the town receives subsidy from the state for every case of tuberculosis hospitalized. In addition to the four hospitalized cases, 22 other cases from Mansfield were examined and x-rayed in the Out-Patient Department and five more examinations with x-ray were given to follow up cases without any additional charge to the town. These facts were not considered by Dr Dunbar. In other words in estimating the cost he employed simple arithmetic but faulty mathematics to arrive at a wrong answer. I should like to state that one of the cases from Mansfield had the benefit of major surgery (thoracoplasty) which resulted in marked improvement in the patient's health and gives promise of a cure. There is no added charge to the town for this major surgery, the value of which should not be lightly estimated. But there is another and more important aspect to this question. Tuberculosis is a widespread disease, very devastating in its effects on the health of the nation being still the major cause of death in young and middle-aged people and its continuance is largely due to the spreader or open case in the community. One open case removed from a town and properly cared for in an institution insures some degree of protection from tuberculous infection to others in that community. Dr Dunbar's method of figuring the cost of the care and treatment of tuberculosis is not greatly unlike that of a man who has to insure his employees and then at the end of the year should one accident occur makes a mathematical computation to show how costly that accident was. In other words he takes no account of any other values involved.

Massachusetts can be proud of what she has accomplished in the campaign against tuberculosis. She is today, due to wise leadership supported by progressively thinking people foremost amongst the states in anti tuberculosis work and I venture to state that of all the undertakings to which people of this country contribute by way of taxation not one has given a richer reward or greater returns for the investment than anti tuberculosis work which includes the tuberculosis hospitals.

The mortality rate from pulmonary tuberculosis in the Bristol County Tuberculosis Hospital Zone dropped from 88 per 100 000 in 1928 to 49 per 100 000 in 1932 a decrease in mortality of 43 per cent in the four year period. No thinking person will deny that hospitalization and modern methods of treatment in the hospital have contributed largely to this reduction in mortality. Has the price been too great?

Finally it must be remembered that when a sin

ADDED FEATURES OF THE PRENDERGAST
PREVENTORIUM

Dr Nathaniel K Wood, Chairman of the Prendergast Preventorium Committee of the Boston Tuberculosis Association, wishes to announce to the medical profession that the Prendergast Preventorium 1000 Harvard Street, Mattapan is equipped to take care of diabetic children, and children suffering from malnutrition, as boarders. The rates are \$10 a week. An extra charge is made to defray the actual cost of insulin used on each diabetic child.

AN INSTITUTE ON HEALTH EDUCATION
IN THE SECONDARY SCHOOLS

The Massachusetts Tuberculosis League and The Southern Middlesex Health Association have issued invitations to attend an Institute on Health Education in the Secondary Schools to be held on Saturday, May 12 at the Winchester High School Main Street and Mystic Valley Highway Winchester, Mass.

The morning session will begin at 10 30 at which Dr C-E A. Winslow of Yale University will deliver an address on Cultural Objectives of Health

RÉSUMÉ OF COMMUNICABLE DISEASES
IN MASSACHUSETTS FOR MARCH, 1934

Measles reached its highest reported incidence for Massachusetts

Diphtheria and typhoid fever give every indication of running lower this year than ever before

Lobar pneumonia and scarlet fever show nothing remarkable

Pulmonary tuberculosis and whooping cough were reported in slightly higher figures than for March, 1933

Epidemic cerebrospinal meningitis, mumps, chicken pox tuberculosis other forms and anterior poliomyelitis show nothing remarkable

RARE DISEASES

Anterior poliomyelitis was reported from Boston, 1, Revere, 1 total 2

Anthrax was reported from Salem, 1

Dysentery (amebic) was reported from Fall River, 2, Ipswich, 1, New Bedford, 1, Salem, 1, Worcester 1 total, 6

Dysentery (bacillary) was reported from Lawrence 2 Taunton, 1, total, 3

Encephalitis lethargica was reported from Clinton, 1 Lawrence, 1, Stoneham, 1, Westfield, 2, total, 5

Epidemic cerebrospinal meningitis was reported from Boston 2 Cambridge, 1, Northampton, 1, Peabody, 1, Southbridge, 1, Springfield, 1 total 7

Malaria (therapeutic) was reported from Taunton, 1

Septic sore throat was reported from Beverly 2, Boston, 5 Brookline 1, Foxboro, 2 Haverhill, 1, Malden, 5 Medford, 5, Milford, 1, Salem 1, Topsfield, 1 total, 24

Tetanus was reported from Fall River, 2

Trachoma was reported from Boston, 2, Revere, 1, total, 3

Trichinosis was reported from Dedham, 1

Typhus fever was reported from Lynn 1

Undulant fever was reported from Southbridge, 1

and as Prof. Chittenden was willing to say a good word in my behalf I was admitted to the second year class and had the privilege of taking my courses in pathology and bacteriology under Dr Welch

The first day he met our class which numbered twenty five he demonstrated the organs obtained that morning at autopsy from a case of acute military tuberculosis His manner of demonstration made the tubercle and tuberculosis seem to me a most fascinating subject of study I had never had a teacher make anything appear so interesting I recall vividly my feelings as I walked out of the room and down the street. As I had not met any of my classmates no one disturbed my thoughts I was convinced by what I had seen and heard that I had made no mistake in coming to Johns Hopkins The famous saying in regard to Mark Hopkins came to my mind and I thought then and I think now, that William H. Welch on one end of a log and a student on the other would make a medical school

During that academic year of 1895-96 Dr Welch gave himself without stint to the students taking his courses in bacteriology and pathology I took full notes of his lectures and demonstrations and when bound they made two goodly sized volumes Fortunately they are preserved and these abstracts of his lectures indicate the wealth of knowledge he gave to his students, and give clear indication of the interesting and systematic way in which he presented the subjects taught I recall that my friend and classmate Walter Steiner was able to take better and fuller notes Two years ago a volume of notes taken by students of Virchow's lectures was published and presented to the members of the German Pathological Society at their annual meeting It has been suggested that a similar memorial volume might be compiled of Welch's lectures

At the end of the academic year on the eve of my return to New England Dr Welch gave me a letter of introduction to Dr Councilman in which he expressed the hope that I might work that summer under Dr Councilman's direction This letter accomplished much for me as it opened wide the door of opportunity to work under Dr Councilman An enthusiasm for the study of pathology instilled by Dr Welch made that summer a very happy one Work done for the love of it was rewarded by an offer from Dr Councilman, before my return to Baltimore of a position in his laboratory on my graduation The lure of pathology as it was studied in the laboratories of Welch and Councilman was so great that I accepted the opportunity for further training without hesitation Dr Councilman became my guide and teacher and one to whom I could always turn for help and advice knowing he would never fail me For this highly prized friendship I owe a great debt to Dr Welch.

The following year as my funds were low Dr Welch made me a student assistant in his laboratory and thereby enabled me to see the work of his department at close range All the details of the

work were in the hands of Dr Flexner and it was he who did the autopsies Dr Welch rarely came to the laboratory until the early afternoon unless a lecture was scheduled In the mental picture of those days I see him as a kindly serene gentleman seated before the microscope of one of the assistants unhurriedly studying a specimen and at the same time asking and answering questions He is smoking a cigar and wearing street clothes unprotected by a laboratory coat. He seemed to me more like an interested visitor than the laboratory head to which office I, the lowliest worker there, assigned in my mind Dr Flexner Dr Welch's ability to work without haste and without waste is shown by the fact that a bibliography of his published writings prepared in 1920 listed 411 articles

Rumor had it that he read far into the night and that breakfast and luncheon were a combined meal His lodgings were on the second floor of a house on St. Paul Street and he took his meals at the Maryland Club nearby His study was lined with books On my first visit to his chambers he showed me Hirsch's Biographisches Lexikon in six volumes and so impressed me with its value that I bought a set as soon as one was available

The last time I saw Dr Welch was at a luncheon in Baltimore in the fall of 1932 He seemed so alert mentally and he appeared so young for his years that I was moved to tell him that he seemed no older than he did when I sat at his feet as a student thirty seven years before "That does not prove a thing," he said, "I may have been senile then"

Dr Welch with characteristic modesty claimed that what he accomplished was largely due to good fortune in arriving on the medical scene at the time he did. If he had begun his life work twenty years earlier it would have been impossible he claimed, to have established pathological laboratories in this country If he had arrived twenty years later the work would have already been done by others It is known however, that opportunity favors the prepared mind Leaving native ability aside no one was so well equipped by education and training as was Welch when he took up his work in New York in 1878 He had graduated third in his class of one hundred and eleven at Yale After matriculating in medicine at P and S he took the unusual step of interrupting his medical studies to return to New Haven where he spent a year in the study of science devoting most attention to organic chemistry During his internship of eighteen months at Bellevue he learned much morbid anatomy from association with Delafield and Janeway He spent two years abroad where he first studied normal histology under Waldeyer at Strassburg and later worked with Ludwig at Leipzig In the second year he carried on his important investigations on the cause of pulmonary edema under Cohnheim in Breslau. There he met Koch then a general practitioner but doing epoch making work in the study of the anthrax bacillus There also he gained much from Weigert

gle case of tuberculosis is hospitalized and properly taken care of (granted that the cost for the individual case is great) not only the patient benefits but the community, and not alone the community of to-day but that of the years ahead.

Yours truly,

GARNET P. SMITH, *Superintendent*,
Bristol Connty Hospital,
Attleboro, Mass

April 28, 1934

A TRIBUTE TO DR. WILLIAM HENRY WELCH
BY DR. JOSEPH H. PRATT, 270 COMMON
WEALTH AVENUE BOSTON MASS

May 6 1934

Dr. Welch had so long been the recognized leader of the medical profession in this country that even men who graduated toward the end of the last century know no other. To many Dr. Welch in the eminence of his position in medical affairs, seemed more like an institution than a mere man. All those who had the happy fortune to know him must have been impressed with his modesty, simplicity, and kindliness. "Some men mellow with age," said Sir Andrew Balfour, 'but Welch I think must have been born mellow and his mellowness has merely ripened with the years.'

Urbanity he certainly possessed and with it that equanimity of spirit which Dr. Osler extolled so highly. He had that quality of detachment that enabled him to accomplish great reforms in medical education without stress and strain and without passion. He criticized the existing order only indirectly by suggesting something better. His early career shows the courage of the man and his indifference to material gain. He turned aside from the allurements of clinical medicine to be the first American to devote his life to pathology. This was a bold step as he had no money and the teaching of pathology, which paid next to nothing, was looked upon simply as a stepping stone to clinical professorship and a consulting practice.

He had the courage to leave his own school, "P and S" in New York, then locally supreme in medicine and to join the faculty of Bellevue as the latter school offered him three rooms for a laboratory and the former nothing.

Later he had the courage to leave metropolitan New York and move to provincial Baltimore. When he did so his friends said he probably would become a connoisseur of terrapin and old Madeira but that his development as a pathologist would suffer. At that time, 1884, there was no Johns Hopkins Hospital and no Johns Hopkins Medical School. Five years later the hospital was opened, and ten years elapsed before he could resume the teaching of pathology to undergraduate students. In Baltimore he had the courage and faith to plan an ideal medical school with entrance requirements so much higher than existed anywhere else in the world that some doubt was entertained whether more than a handful of students would apply for admission. His plan was accepted from a number submitted

and the School began its first year with eleven students. The pathological building on the hospital grounds with the addition of two stories was added to the medical school. Laboratories of anatomy, physiological chemistry and physiology were housed in that building until a new one was constructed the following year.

During his New York days he resisted two temptations that reveal something of the character of the man. He had been less than six months at Bellevue when the alumni of the College of Physicians and Surgeons raised money for a pathological laboratory and the direction and use of this laboratory was offered to Dr. Welch. He declined the post and characteristic helpfulness suggested the name of a friend, Prudden, whom he considered best qualified for the position. In a letter to Prudden, fortunately preserved and quoted by Dr. Flexner in his delightful biographical sketch of Welch, he wrote: "Deafield proposed that I should go as his first assistant and have charge of the histological department and assist him as much as necessary in the pathological part. The salary was to be five hundred dollars for the first year, and I believe more subsequently. I was naturally delighted with the offer and thought it was just what I wanted, an opportunity to work in the direction where I had studied most. Upon speaking of the matter before coming to a decision, with some of the professors at Bellevue, I find they are reluctant to have me leave them and even represent it as not the square thing for me to go at present. The latter motive especially influenced me to stay, as I do not believe it pays to do anything unfair. I feel as if I were relinquishing a great opportunity and do not see any equivalent for it at present at Bellevue."

It was not long before Dr. Welch found great favor with Prof. Austin Flint, the leading American physician of that generation. He wrote the section on pathology for the fifth and sixth editions of Flint's book on the practice of medicine, then the leading American textbook. Dr. Flint wrote clearly and well and Dr. Flint insisted that Dr. Welch's style of presentation was so similar to his own that he had difficulty in deciding whether he or Welch had written certain sections. Dr. Flint wanted Welch to be his successor and would have made him clinical professor of medicine but Welch declined to be considered for the position as it would have blocked the advancement of E. G. Janeway. When told of this incident by Dr. Welch, I gained the impression that Dr. Janeway never knew that he owed his professorship at Bellevue to the self-sacrifice of his friend.

Dr. Welch was the first dean of Johns Hopkins and to him I appealed when I sought to enter the school. He was loath to admit anyone to advance standing as he felt that if the school was to attain its high goal, better instruction must be given than was obtainable in any other institution existing at that time. Contact with men, not courses and credits counted with him. The fact that I had worked a year with Professor Chittenden 'merited special consideration in your case,' Dr. Welch wrote me.

ANNUAL MEETING OF THE AMERICAN ASSOCIATION FOR THE STUDY OF GOITER

This meeting will be held in Cleveland, Ohio, June 7, 8, 9, 1934

Scientific sessions are open to any members of the medical profession in good standing

Registration fee \$2 00

For details of the program apply to Dr J R. Yung, Terre Haute, Ind

NEW ENGLAND HEART ASSOCIATION

The next meeting of the New England Heart Association will be held in the Peters House of the Rhode Island Hospital, Providence, R I, Monday, May 21 at 8 15 P M

All members of the New England Heart Association and interested physicians are invited to attend.

SPECIAL LECTURESHIP UNDER THE AUSPICES OF THE NEW ENGLAND HEART ASSOCIATION

Dr Frank N Wilson of the University Hospital, University of Michigan will give two lectures at the Boston Medical Library (John Ware Hall) at 4 30 P.M., May 24 and 25, 1934

May 24 When Is an Electrocardiographic Examination Indicated and What Sort of Help Can It Give?

May 25 The Electrocardiographic Diagnosis of Myocardial Infarction

Physicians and medical students are invited to attend.

Annual Meeting Friday, May 25 at 4 00 P M

NEW ENGLAND PHYSICAL THERAPY SOCIETY

ANNUAL MEETING

The annual meeting of the New England Physical Therapy Society will be held in Sprague Hall, Boston Medical Library, 8 Fenway, at 8 P.M., on Wednesday, May 16

PROGRAM*

Subject Physical Medicine.

(a) Electrotherapy (with motion pictures)
William D McFee M.D Boston.

(b) Electrosurgery Halsey D Loder, M.D., Boston

Discussion will be opened by Franklin P Lowry, M.D of Newton, and Lester R Whitaker, M.D, of Boston.

Prior to the program there will be a brief business session at which officers will be elected for the ensuing year, and such other matters considered as may properly come before the annual meeting

The Executive Council will meet at 7 45 P.M

Members are asked to note the *change in place of meeting*

In charge of Dr William D McFee M.D

and Ehrlich who were fellow workers in Cohnheim's laboratory. Before returning to America he did more work in experimental pathology under von Recklinghausen.

Our debt to Welch was well expressed by Osler when he wrote, "No man of his generation in the United States has so deeply influenced the profession, not only by his administrative ability and his stimulating work in pathology, but much more by a personal, unselfish devotion to its highest interests."

RECENT DEATHS

ENSWORTH—WILLIAM HOWARD ENSWORTH, M.D., of 40 Princeton Street, East Boston, died at his home, May 3, 1934. He was born in East Boston, October 13, 1865, the son of Charles P., and Hannah Howard Ensworth. His early education was acquired in the schools of East Boston, and he graduated in medicine from the Harvard Medical School in 1888. He joined the Massachusetts Medical Society in 1888, and was a Fellow of the American Medical Association. He was active in Masonic circles.

He is survived by a sister, Mrs. Adelaide Gouge of Halifax, Nova Scotia, and a nephew, Marcus Ensworth of Watertown, Massachusetts.

RIPLEY—WILLIAM LITTLEFIELD RIPLEY, M.D., of 9 Oak Square, Brighton District, Boston, Massachusetts, died at his home, May 1, 1934. Dr. Ripley was born in Boston in 1872, the son of Eliab and Frances Littlefield Ripley, and among his ancestors was Elder Brewster of the Mayflower.

His premedical education was acquired at the Worcester Academy and Tufts College, and he received his M.D. degree from Tufts College Medical School in 1903.

He was a Fellow of the Massachusetts Medical Society having joined in 1903.

He had taught physiology at Tufts for a short time and carried on a large general practice with especial interest in x-ray work.

He was a member of the Ancient and Honorable Artillery Company, the Fusiliers, the Army and Navy Club, the Presentation Club of Brighton, the Catholic Order of Foresters and the Newton Lodge of Elks.

He is survived by his widow, Mrs. Alice Turnbull Ripley, eight children, William, Franklin, Miss Geraldine, Robert, Miss Stella, Miss Virginia, Charles and Vincent. A brother and sister also survive him.

OBITUARY

A TRIBUTE TO ARTHUR L. CHUTE, M.D.

In the death of Dr. Arthur Lambert Chute, which occurred on January 12, 1934, the New England Branch of the American Urological Association loses one of its most distinguished members and many of

us, the valued friend and counsellor of many years.

Dr. Chute was one of the earliest of the Boston members of the American Urological Association and a founder of the New England Branch Society. He had served as President of both of these organizations, as well as President of the American Association of Genito-Urinary Surgeons, and Chairman of the Section of Urology of the American Medical Association.

He early gave his attention to the study of urological conditions and was one of the first men in Boston to specialize definitely in this branch of surgery. Some of the earliest, if not the first cystoscopic examinations and ureter catheterizations by the indirect method made in Boston, were done by him at the Boston Dispensary.

He was a tireless worker, a clear thinker, and a prolific writer. His publications were all along clinical lines and based on extensive personal experience and observation. He was among the first to stress the importance of pre-operative treatment of prostatics, the free use of hypodermoclysis and the two-stage prostatectomy. He was also among the earliest and staunchest advocates of spinal anesthesia in prostatic surgery. One of his outstanding traits was a most useful and wholesome skepticism of new and untried methods, although among the first to adopt anything of proved worth.

He rarely missed a medical meeting and one of his greatest pleasures was contact with his colleagues where his geniality, his sense of humor, and his keen and kindly comments made him a delightful companion. His ideals and standards were of the highest and his devotion to his patients, his practice, his family, and his friends, is an example and inspiration to all who knew him.

He is survived by his widow and three children: Dr. Richard Chute of Boston, Mrs. Samuel McMurtrie of New York, and Oliver Swift Chute of Whitinsville, to whom the members of the Society offer the most sincere sympathy in their as well as our own irreparable loss.

ARTHUR H. RING, M.D., *Secretary*

BERKSHIRE DISTRICT MEDICAL SOCIETY

The Berkshire District Medical Society will hold its annual meeting at the Berkshire Hunts Club at Lenox on the evening of May 14. Dinner will be served at six thirty.

The speaker on this occasion will be Dr. John St. John of New York. The subject, "A Twenty Five Year Study of Cancer of the Stomach."

HUGH J. DOWNEY, M.D., *Secretary*

THE NEW ENGLAND ROENTGEN RAY SOCIETY

The May meeting will be held Friday night, May 18, 1934, at the Boston Art Club, Boston, Mass., at 8 P.M.

The Annual Dinner will be held at the Boston Art Club at 6 45 P.M.

SCIENTIFIC SESSION

"The Value of Roentgenography in the Diagnosis of Laryngeal Disease" Chevalier L. Jackson, M.D., Philadelphia, Pa.

THOMAS R. HEALY, M.D., *Secretary*,
370 Marlborough Street, Boston, Mass.

THE HARVARD MEDICAL SCHOOL ALUMNI ASSOCIATION

The Annual Meeting of the Harvard Medical School Alumni Association will be held Saturday, May 12. Ward rounds (10 a.m. to 12 m.) and operations will be held at the Peter Bent Brigham, the Massachusetts General and the Boston City Hospitals. A business meeting and luncheon (\$1.00) will be held in the gymnasium of Vanderbilt Hall at 12 30 p.m.

SOCIETY MEETINGS, CONGRESSES AND CONFERENCES

May 10—Massachusetts General Hospital will hold a Clinical Meeting of the Staff in the Moseley Memorial Building at 8 15 P.M.

May 11—William Harvey Society will meet in the Auditorium of the Beth Israel Hospital at 8 P.M.

May 12—Institute on Health Education in the Secondary Schools. See page 1036.

May 12—Harvard Medical Alumni Association. See notice above.

May 14, 15, 16, and 17—Thirtieth Annual Meeting of the National Tuberculosis Association. For details apply to the National Tuberculosis Association, 450 Seventh Avenue, New York City.

May 15—South End Medical Club will meet at the office of the Boston Tuberculosis Association, 554 Columbus Avenue, Boston, at 12 noon.

May 15—New England Physical Therapy Society. See page 1041.

May 15—New England Obstetrical and Gynecological Society will hold its spring meeting at Portland, Maine. The registration of members will take place at the Maine General Hospital from 9 A.M. until 1 P.M. and in the afternoon at the Chamber of Commerce Building, 142 Free Street from 2 P.M. until 5 P.M.

FRED J. LYNCH, M.D.

475 Commonwealth Avenue, Boston.
May 18—The New England Roentgen Ray Society. See notice above.

May 19—The New England Pediatric Society will meet at New Haven, Conn., at 2 30 P.M. Information may

be obtained from the Secretary, Dr. Gerald Hoeftel, 319 Longwood Avenue, Boston.

May 21, 24, 25—New England Heart Association. See page 1041.

May 26, 27, 28, and 29—The American Association on Mental Deficiency. Details may be obtained from the Secretary, Dr. Groves B. Smith, Godfrey Illinois.

June 7, 8, 9—Annual Meeting of the American Association for the Study of Golter. See page 1041.

June 12—American Heart Association will meet at 9 30 A.M. at the Cleveland Hotel, Cleveland, Ohio.

July 24-31—The IVth International Congress of Radiology will be held in Zurich under the presidency of Professor H. R. Schnitz. General Secretary Dr. H. E. Walther, Gloriastrasse 14, Zurich.

August 18 - September 30—Medical Study Trip to Hungary. See page 975, issue of May 10.

September 3-6—American Public Health Association at Pasadena, California. Dr. J. D. Dunshie, Chairman, Local Committee on Arrangements.

September 4, 5, 6—International Union Against Tuberculosis. For information address the National Tuberculosis Association, 450 Seventh Avenue, New York City.

BOOK REVIEWS

The Life of Sir Robert Jones. By Frederick Watson. 318 pp. Baltimore: Williams & Wilkins Company. \$3.75.

The Life of Sir Robert Jones by Frederick Watson, son of Ian MacLaren and son-in-law of Sir Robert, is one of the great medical biographies of our time. Affection prompted it, intimate knowledge made it possible, and a facile pen wrote it. All these three activating factors were necessary if the world was to have a true picture of one of the greatest of surgeons, and the most lovable of men.

The biographer has had access to family chronicles and personal letters, to war documents and plans of medical organization. With his own eyes he has watched the dreams of this happy and valiant warrior reach a fruition rarely realized in the life time of the dreamer.

Rehabilitation of the wounded soldier, of the handicapped civilian, and of the crippled child was the passion of this most famous of orthopedic surgeons. Throughout the book the strength and sweetness of Sir Robert's character are evident in all his thoughts and plans and acts.

It is an inspiring book not less for civilians than for physicians and medical students. It stimulates hero worship of the finest type. There is wealth of fascinating anecdote and stirring struggle, of close friendship and warm family life. The side-lights on noted men and women of our day are illuminating and well directed.

There was an earlier recognition of Sir Robert's originality and eminence in America than in England. Many American surgeons have experienced his priceless friendship.

The epilogue, 'The Personality of Robert Jones,' is a fitting contribution by the author who elsewhere scarcely appears in the book so vivid is the narrative and so successful has Mr. Watson been in submerging his own personality in that of his great subject.

A Bureau of Information will be maintained by the Committee of Arrangements during the meetings in the lobby of the Hotel Bancroft
Parking in the streets in the vicinity of the

hotel is restricted. Fellows are advised to use the parking spaces in the rear of the hotel reached by Portland and Federal Streets, or one of the three large garages which are within one or two minutes' walk.

Fellows are requested to register as soon as they arrive and to get their tickets to the Buffet Luncheon and the Annual Dinner on Tuesday, and the Buffet Luncheon on Wednesday. The charge for the Annual Dinner will be \$2.00 to those whose dues have been paid.

On Tuesday, luncheon will be served at a cover charge to those not members of the Council, on Wednesday, without charge to those who are not in arrears.

The Worcester District Medical Society, at its Annual Meeting on Wednesday, May 9, very generously voted to assume the expense of entertainment for the Fellows and their wives. The Local Committee of Arrangements has arranged with the Worcester, Tatnuck and Wachusett Country Clubs to permit us to play golf on their links at any time during the three days of the meeting. The District Society has also arranged entertainment for the ladies on June 4 and 5. Under the care of a committee of ladies of the Worcester District Society visiting ladies will be taken in busses to the chief points of interest in the city and vicinity, including the new Auditorium, the Higgins Armory, where a very remarkable collection of armor is on exhibition, the Worcester Art Museum, where many fine works of art are on display, and some of the beautiful gardens in and about Worcester. They will also be entertained at luncheons, both Monday and Tuesday, at the Worcester Country Club. Full details will be furnished by the Chairman of the Local Committee of Arrangements, Dr. Edwin R. Leib, 36 Pleasant street, Worcester. Fellows are cordially invited to bring their wives to Worcester.

The Scientific Exhibits will be in the small ballroom immediately back of the main ballroom of the Hotel Bancroft and also on the mezzanine floor above the ballroom and the lobby. See page 1047 for list of exhibits.

The Commercial Exhibits will occupy the lobby of the hotel, the dining room, and the ballroom assembly immediately off the main ballroom. A list of the exhibitors will be found on page 1049.

MONDAY MORNING, JUNE 4

9 30 to 12 30 O'Clock

There will be dry clinics at the following hospitals: Belmont Hospital, Belmont Street, Fairlawn Hospital, 189 May Street, Memorial Hospital, 119 Belmont Street, St. Vincent Hospital, 73 Vernon Street, Worcester City Hospital, 71 Jacques Avenue, Worcester Hahnemann Hospital, 281 Lincoln Street, Worcester State Hospital, Belmont Street.

CLINIC PROGRAMS

MEMORIAL HOSPITAL—JUNE 4, 1934

10 00 A M—12 30 P M

10 00-11 00—*Obstetrical Service*

Single Blade Forceps Rotation—Moving Pictures

Abruptio Placentae—Case Reports with lantern slides

Drs G C Lincoln, J W O'Connor, J E Talbot

Medical Service

Ward Rounds

Demonstration of Unusual Cardiac Cases with Electrocardiograms

Drs O H Stansfield and E J Halloran.

10 30-12 30—*Pediatrics Service*

(1) Demonstration of Interesting Cases of Blood Dyscrasia

(2) Mongolism in Twins—case

(3) Muscular Dystrophy—cases

(4) Children's Diabetic Manual

(5) Pasteurization—efficiency

(6) Modified Home Oxygen Tent

(7) Portable Cubicles

Drs C A. Sparrow, A M Kimberly, H Talamo

11 00-12 00—*Radiology*

Treatment of Skin Cancer—Cases and lantern slides

Dr R. Dresser

11 00-12 30—*Nose and Throat Service*

Bronchoscopy

Cleft Palate

Tonsil Operative Technique

Drs Gordon Berry, H J Gibby, A. L.

Caron, H B Goodspeed

Surgical Service

Varicose Veins—Saphenous Ligation

Abdominal Menstrual Fistula—Case Operations

Drs W C Seelye, B H Alton D S

Adams, C T Smith, B C Wheeler

12 30—Luncheon

WORCESTER CITY HOSPITAL

JUNE 4, 1934

10 00 A M—12 30 P M

10 00-12 00 A M—Winslow Surgery—Surgical Clinic Dr B F Andrews and members of Surgical Staff

Participating in the Clinic Dr F H Lahey and associates presenting brain surgery, surgery of the colon and surgery of the gallbladder

10 00 A M—Thayer Hall—Medical Clinic Amoebic Dysentery Presentation by Dr Percy A Brooke

Pohomyelitis Presentation by Dr James A Givan

Diseases of the Blood Presentation by Dr Raymond H Goodale

Heart Disease Presentation by Dr Frank B Carr

Diabetes Presentation by Dr A Wilson Atwood,

Participating in the Clinics Dr Elliott P Joslin, Boston, Dr Burton E Hamilton, Boston, Dr William Dameshek, Boston, and others

12 30 P.M.—Thayer Hall—Luncheon

Details for the other hospital clinics will be announced later

The luncheons at the various hospitals, following these clinics are to be served through the courtesy of the Worcester District Medical Society

MONDAY AFTERNOON, JUNE 4

2 30 O'Clock

Hotel Bancroft, Crystal Room

SECTION OF PEDIATRICS

Officers of the Section

Dr Gardner N Cobb, Worcester, *Chairman*

Dr James M Baty, Boston, *Secretary*

1 *The Use of the Ketogenic Diet in Pyuria*

By Dr Warren E Wheeler, Massachusetts General Hospital, Boston (By invitation.)

Discussion to be opened by Dr Fritz B Talbot, Boston

2 *Present Status of Vaccination Against Tuberculosis*

By Dr Clement A Smith, Children's Hospital, Boston (By invitation.)

Discussion to be opened by Dr Eliot H Luther, Westfield, and Dr Arnold Branch, Boston. (By invitation)

3 *The Role of the Streptococcus in So-called Sudden Death in Infancy and Childhood*

By Dr Sidney Farber, Harvard Medical School, Boston (By invitation)

Discussion to be opened by Dr Richard M Smith, Boston, and Dr Karlton G Percy, Chestnut Hill and Boston

4 *Pyogenic Infection of Bones and Joints in Infants*

By Dr William T Green, Children's Hospital, Boston

Discussion to be opened by Dr Frank R Ober, Boston, and Dr Henry W Hudson, Jr, Waban and Boston

MONDAY AFTERNOON, JUNE 4

2 30 O'Clock

Hotel Bancroft Ballroom

SECTION OF RADIOLOGY AND PHYSIOTHERAPY

Officers of the Section

Dr Charles W Blackett, Newtonville and Boston, *Chairman*

Dr Franklin P Lowry, Newton *Secretary*

1 *A Method of Reduction and Fixation of Intracapsular Fractures of the Femoral Neck*

By Dr Joseph H Fay, Melrose

Discussion to be opened by Dr Ralph D Leonard, Melrose and Boston

2 *The Conduct of the Convalescent Stage of Anterior Poliomyelitis*

Motion pictures showing a new method of muscle re-education

By Dr Harold D Corbusier, Plainfield, New Jersey (By invitation)

Discussion to be opened by Dr Frank R Ober, Boston

3 *Diverticulosis, Diverticulitis and Carcinoma of the Colon A Roentgenologic Discussion*

By Dr Ross Golden, New York, N Y (By invitation)

Discussion to be opened by Dr Richard B Cattell, Boston, Dr Merrill C Sosman, Boston, Dr Philip H Cook, Worcester

4 *Physical Therapy in the Treatment of Athletic Injuries*

By Dr Thomas K Richards, Boston

Discussion to be opened by Dr Otto J Hermann, Brookline and Boston

MONDAY EVENING JUNE 4

8 O'Clock

Hotel Bancroft, Ballroom

THE SHATTUCK LECTURE

By Dr Warfield T Longcope, Baltimore, Physician-in-Chief, The Johns Hopkins Hospital

Subject *The Importance of Disturbances in Nutrition in Oedematous States* (Illustrated by lantern slides)

Light refreshments will be served after the lecture

TUESDAY MORNING, JUNE 5

9 15 O'Clock

Chamber of Commerce Hall

SECTION OF SURGERY

Officers of the Section

Dr Ernest M Daland, Boston, *Chairman*

Dr Joseph H Shortell, Boston, *Secretary*

1 *Cancer of Rectum and Lower Bowel Case Problems and Methods*

By Dr Ernest L Hunt, Consulting Surgeon, Worcester City Hospital

Discussion to be opened by Dr F B Sweet, Springfield and Dr Benjamin H Alton Worcester

2 *Total Ablation of Thyroid Gland for Intractable Heart Disease Medical and Surgical Aspects*

By Dr Herrman L Blumgart, Boston, Associate Professor of Medicine, Harvard Medical School, and Visiting Physician, Beth Israel Hospital, and Dr David D Berlin, Boston, Assistant Professor of Anatomy, Tufts College Medical School, and Surgeon to Thyroid Clinic, Beth Israel Hospital

Discussion to be opened by Dr Howard M Clute of the Lahey Clinic, Boston, and Dr Robert C Cochrane, Surgeon-in-Chief, Second Surgical Service, Boston City Hospital

3 *Trans-Urethral Resection of the Prostate*

By Dr Herman C Bumpus, Jr, New York Recently at the Mayo Clinic, Rochester, Minnesota (By invitation)

Discussion to be opened by Dr Roger C Graves, Visiting Urologist, Carney Hospital, and Genito-Urinary Surgeon, Pondville Hospital, and Dr Walter D Bieberbach, Worcester, Urologist to Worcester City Hospital

4 *Management of Fractures About the Ankle Joint*

By Dr Clay Ray Murray, New York, Assistant Professor of Surgery, College of Physicians and Surgeons, Columbia University (By invitation)

Discussion to be opened by Dr Frederic J Cotton, Boston, Consulting Surgeon, Boston City Hospital, and Dr Charles L Scudder, Boston, Honorary Surgeon, Massachusetts General Hospital

TUESDAY MORNING, JUNE 5

11 30 O'Clock

Hotel Bancroft, Ballroom

ANNUAL MEETING OF THE SUPERVISING CENSORS

TUESDAY NOON

Hotel Bancroft, Ballroom

ANNUAL MEETING OF THE COUNCIL

Followed by the Cotting Luncheon to Councilors in the Chamber of Commerce Hall.

Other stated meetings in John Ware Hall, Boston Medical Library, 8 Fenway, at noon, on the first Wednesdays of October and February

TUESDAY AFTERNOON, JUNE 5

1 O'Clock

Chamber of Commerce Hall

A buffet luncheon will be served to Fellows who have tickets (Procurable at Registration Desk Price \$1 00)

2 30 O'Clock

Chamber of Commerce Hall

SECTION OF MEDICINE

Officers of the Section

Dr George R Minot, Boston, *Chairman*

Dr Herrman L Blumgart, Boston, *Secretary*

1 *The Social Conditioning of the Visceral Activities*

By Dr Abraham Myerson, Boston, Professor of Neurology, Tufts College Medical School, Director of Research, Boston State Hospital, Senior Visiting Neurologist, Boston City Hospital and Beth Israel Hospital

Discussion to be opened by Dr Lawrence K Lunt, Carlisle and Concord

2 *Cancer and the General Practitioner*

By Dr Henry Jackson, Jr, Chestnut Hill and Boston, Assistant Professor of Medicine, Harvard Medical School, Associate Physician, Thorndike Memorial Laboratory, and Junior Visiting Physician, Boston City Hospital, Physician, Pondville Hospital

Discussion to be opened by Dr P E Truesdale, Fall River

3 *Chronicity of Rheumatic Fever*

By Dr Homer F Swift, New York, Member of the Rockefeller Institute for Medical Research (By invitation)

Discussion to be opened by Dr Paul D White, Boston, and Dr Oliver H Stansfield, Worcester

4 *Tuberculosis as It Affects the Physician's Practice*

By Dr Henry D Chadwick, Boston, Massachusetts Commissioner of Public Health

Discussion to be opened by Dr Brace W Paddock, Pittsfield

TUESDAY EVENING, JUNE 5

7 O'Clock

Hotel Bancroft, Ballroom

THE ANNUAL DINNER

Fellows wishing to sit together at the dinner will please send their names to Dr Edwin R Leib, *Chairman of the Local Committee of Arrangements*, 36 Pleasant Street, Worcester, at the earliest possible date and proper reservations will be made. Tickets for the dinner should be obtained at the Registration Desk. The galleries of the ballroom will be reserved for ladies who wish to hear the distinguished after-dinner speakers

WEDNESDAY MORNING, JUNE 6

9 O'Clock

Chamber of Commerce Hall

SECTION OF OBSTETRICS AND GYNECOLOGY

Officers of the Section

Dr Joseph W O'Connor, Worcester, *Chairman*
Dr Thomas Almy, Fall River, *Secretary*

- 1 *Prolan Therapy in Abnormal Uterine Bleeding* (Illustrated by lantern slides)
By Dr Joe Vincent Meigs, Boston, Gynecologist

Discussion to be opened by Dr Frank A. Pemberton, Boston, Gynecologist and Dr Charles H Lawrence, Jr, Boston, Internist

- 2 *Intracranial Hemorrhage in the New Born from the Standpoint of the General Practitioner* (Illustrated by lantern slides)

By Dr P Brooke Bland, Professor of Obstetrics, Jefferson Medical College, Philadelphia (By invitation)

Discussion to be opened by Dr Alonzo K Paine, Boston, Obstetrician, Dr Richard S Benner, Springfield, Obstetrician, and Dr Randolph K Byers, Milton and Boston, Pediatrician

- 3 *Radium Therapy in Uterine Hemorrhages of Benign Origin—An Analysis of the End-Results of 150 Consecutive Cases* (Illustrated by lantern slides)

By Dr Louis E Phaneuf, Boston, Gynecologist

Discussion to be opened by Dr Samuel R Meaker, Boston, Gynecologist, and Dr Richard Dresser, Chestnut Hill and Boston, Radiologist

WEDNESDAY MORNING, JUNE 6

9 O'Clock

Hotel Bancroft, Crystal Room

SECTION OF TUBERCULOSIS

Officers of the Section

Dr Roy Morgan, Westfield, *Chairman*
Dr Donald S King, Boston, *Secretary*

Symposium on Measurement of Activity in Pulmonary Tuberculosis (Papers limited to eight minutes each)

- 1 *Symptoms*

Dr Harvey S Wagner, Barnstable County Sanatorium, Pocasset

- 2 *Physical Signs*

Dr Frank H Hunt, Boston Sanatorium, Mattapan

- 3 *X-ray*

Dr Olin S Pettingill, Essex County Sanatorium, Middleton

- 4 *Quantitative Tuberculin Tests*

Dr Theodore L Badger, Boston City Hospital

- 5 *Leucocyte Picture*

Dr Jacob Kaminsky, Middlesex County Sanatorium, Waltham

- 6 *The Monocyte-Lymphocyte Ratio*

Dr Gulh Lindh Muller, Rutland State Sanatorium

- 7 *Schilling Differential Count and Red Cell Sedimentation Rate*

Dr John W Cass, Jr, The Channing Home, Boston

- 8 *Discussion and Summary of the Whole Problem with Especial Reference to the Study of the Leucocyte Count in Pulmonary Tuberculosis*

Dr William H Ordway, Physician-in-Charge, Metropolitan Life Insurance Company Sanatorium, Mt McGregor, New York State (By invitation)

WEDNESDAY NOON, JUNE 6

Hotel Bancroft, Ballroom

ANNUAL MEETING OF THE SOCIETY

BUSINESS OF THE ANNUAL MEETING

A draft, second revision, of the By-Laws has been sent to every Fellow, under the terms of Chapter VI, Section 3, and Chapter IX of the By-Laws

WEDNESDAY AFTERNOON, JUNE 6

1 O'Clock

Hotel Bancroft, Ballroom

THE ANNUAL DISCOURSE

By Dr Lincoln Davis Boston, Consulting Surgeon, Massachusetts General Hospital, President, Boston Medical Library

Subject *The Objectives of Medical Progress*

WEDNESDAY AFTERNOON, JUNE 6

2 O'Clock

Chamber of Commerce Hall

Buffet Luncheon to all with tickets

Thus will end the Annual Meeting

SCIENTIFIC EXHIBITS

- 1 *Some Effects of Liver Extracts Injected Intramuscularly* By Dr William Parry Murphy, Boston, Instructor in Medicine, Harvard Medical School Illustrated by charts and moving pictures

- 2 *Postgraduate Medical Instruction in Massachusetts* By the Massachusetts Medical Society, Committee on Postgraduate Medical Instruction Dr Leroy E Par-

- kins, Boston, Secretary The past year's experience in postgraduate instruction will be shown in graphic form, together with an outline of next year's program.
- 3 *Polomyelitis—its pathology, epidemiology and after-care* By Dr A. T. Legg, Boston, Assistant Professor of Orthopedic Surgery, Harvard Medical School, Dr W. L. Aycock, Boston, Director of Research, Harvard Infantile Paralysis Commission, and Janet B. Merrill, Boston, Director of Physical Therapeutics, Harvard Infantile Paralysis Commission and Children's Hospital. In addition to statistical charts and models, a moving picture will be shown to illustrate the management of a case from the beginning of the orthopedic treatment.
 - 4 *The Modern Conception of Gonorrhea* By the American Social Hygiene Association and the Neisserian Medical Society of Massachusetts. Dr M. J. Exner, New York, N. Y. (By invitation.) There will be charts illustrating all the phases of diagnosis and treatment. This material has been prepared by Dr Edward L. Keyes, Dr Emily D. Barringer, Dr Erick Langer, Dr P. S. Pelouze, Dr Anson Clark and others. The exhibit won first honors at the American Medical Association meeting in 1933.
 - 5 *The Control of Diabetes* By the Metropolitan Life Insurance Company. Dr Louis I. Dublin, third vice-president and statistician, and the George F. Baker Clinic of the New England Deaconess Hospital, Dr Elliott P. Joslin, Boston, Medical Director. This will be a revision and enlargement of the exhibit shown at the American Medical Association meeting, illustrated by charts and lantern slides.
 - 6 *Treatment of Intractable Congestive Failure and Angina Pectoris by Total Ablation of the Normal Thyroid Gland* By Dr H. L. Blumgart, Boston, Associate Professor of Medicine, Harvard Medical School. There will be charts demonstrating the technique of treatment, the therapeutic results, biochemical and electrocardiographic studies, and moving pictures of the various aspects of thyroidectomy. The exhibit will represent the work of Dr Blumgart, Dr A. A. Weinstein, Dr David Davis, Dr J. E. F. Riseman, and Dr D. D. Berlin.
 - 7 *Fungi Pathogenic to Man* By Dr John G. Downing, Newton and Boston, Assistant Professor of Dermatology, Tufts College Medical School, W. H. Weston, Professor of Cryptogamic Botany, Harvard University, and Sarah M. Cousins, Harvard School of Biology. (By invitation.) The organisms from the simplest forms to the most complex pathogens will be shown growing in culture, together with microphotographic enlargements of their appearance in culture and in tissue lesions, and photographs of the characteristic lesions produced.
 - 8 *Lobar Pneumonia, Its Treatment, and the Neufeld Method of Pneumococcus Typing* By the Massachusetts Department of Public Health, Division of Communicable Diseases, Dr G. W. Anderson, Waban and Boston, Director, and Dr Roderick Heffron, Boston, Director of Pneumonic Study. In addition to the graphic presentation of the results of the recent special pneumonia study in this state, there will be demonstrations of the technique of rapid pneumococcus typing.
 - 9 *Arthritis* By the Massachusetts Department of Public Health, Division of Adult Hygiene, Dr H. L. Lombard, Newton Centre and Boston, Director. There will be gross specimens demonstrating the various types of arthritic pathology, with statistical charts prepared by the Division of Adult Hygiene.
 - 10 *Cancer* By the Massachusetts Department of Public Health, Dr G. W. Taylor, Brookline and Boston, Surgeon at Pondville Hospital, Dr Shields Warren, Boston, Pathologist to Pondville Hospital, and Dr H. L. Lombard, Newton Centre and Boston, Director, Division of Adult Hygiene. Lantern slides, photographs and x-rays of characteristic lesions showing results of various therapeutic measures, and statistical charts of the incidence, curability and mortality rates of cancer in its several forms.
 - 11 *Silicosis and Tuberculosis in Granite and Foundry Workers* By the Massachusetts Department of Public Health, Division of Tuberculosis, Dr A. S. Pope, Newtonville and Boston, Director. The results of the study made by the special Industrial Disease Commission of 1933.
 - 12 *Social Aspects of Medicine* By a Committee of the Harvard Medical School on the Social Aspects of Medicine, and the Chiefs of the Social Service Department of the Boston City Hospital, the Massachusetts General Hospital, the Beth Israel Hospital, and the Children's Hospital. This exhibit illustrates the value of an understanding of the social aspects of medicine to diagnosis, prognosis, therapy and prevention of disease.

CENSORS' MEETINGS

The Censors for the several districts will meet for the examination of applicants for fellow-

ship on the first Thursdays of May and November

The Censors for the Suffolk District will examine applicants residing in that district and also applicants who are non-residents of Massachusetts

Applicants for fellowship should apply to the Secretary of the District Society of the district in which they reside (have a legal residence) at least two weeks before the date of a given examination, taking with them their diplomas

TREASURER'S NOTICE

Assessments, payable in advance, should be paid to the District Treasurers, or, in the case of non-residents, to the Treasurer

Assessments were due January first For the convenience of Fellows who have not yet paid, such assessments will be received for the Treasurer at the Registration Desk in the lobby of the hotel

SECRETARY'S NOTICE

All communications as to membership, especially changes of residence and address, should be sent to the Secretary, who keeps a constantly corrected official list of the Fellows and their addresses

THE JOURNAL

The *New England Journal of Medicine*, the official weekly organ of the Society, will be sent only to Fellows who have paid their assessments, and to such Retired Fellows as may apply for it Address communications to the Managing Editor of the *Journal*, Dr Walter P Bowers, 8 Fenway, Boston

Society Headquarters,
8 Fenway, Boston

COMMERCIAL EXHIBITS

Booth No

- 1—The P L Rider Company, 9 Norwich Street, Worcester, Massachusetts

The P L Rider Company, jobbers of general hospital supplies will display a complete line of Instruments and Specialties L H Marsden of Worcester will be in charge

- 2—The Medical Protective Company, Wheaton, Illinois

Provides professional protection exclusively A F Fox and F G Lockwood in charge of the exhibit, will be at your service

- 3—Tailby-Nason Company, Boston Massachusetts

Manufacturers of Nason's Palatable Cod Liver Oil The Giant Cod and photographs of the Lofoten Fisheries in Norway will be an interesting part of the exhibit.

- 4—The Kellogg Company, Battle Creek, Michigan

Manufacturers of ready-to-eat cereals and Kaffee Hag Coffee Kaffee Hag Coffee will be served and all delegates are invited to call at the booth have a sample and see the caffeine exhibit Mary I Barber, Director of Home Economics will be in charge

- 5—General Electric X-Ray Corporation, 624 Beacon Street, Boston, Massachusetts

Manufacturers of x-ray and electro-medical apparatus Shock proof x-ray apparatus, x-ray films an Inductotherm and minor equipment will be displayed J W Moulton of Springfield will be in charge

- 6—The Brookhill Laboratories, Genesee Depot, Wisconsin

A new method of preparing Concentrated Acidophils Milk is to be introduced R E Sampson of the Brookhill Agency, Boston, will be present to explain details of manufacturing processes

- 7—Kilham & Maleod, 56 Central Avenue, Lynn, Massachusetts

Exclusive New England distributors for Lepel High Frequency Laboratories of New York A complete line of physical therapy equipment will be displayed showing the latest development notably the new combination quartz ultra violet lamps and cold ultra violet lamps, a high powered diathermy equipment in one combination unit also the latest miniature quartz ultra violet lamps for internal use An all purpose electrode surgical unit capable of doing all types of electrode surgery including transurethral prostatic resection and combination short wave diathermy and electrode surgical units

- 8—Westinghouse X-Ray Company, Inc Long Island City, New York

Manufacturers of electro-medical apparatus A new line of our x-ray accessories together with the Westinghouse new Model G" Endotherm will be displayed

- 9—Lederle Laboratories, Inc, 511 Fifth Avenue, New York, New York

This exhibit will present the more important Biological and Pharmaceutical Products which they manufacture Among the Biological Products which will be shown are Pol len Antigens which for twenty years have proved successful in controlling attacks of hay fever Poison Ivy Extract in almond oil for Rhus Dermatitis Antipneumococcic Serum for pneumonia the single dose Toxoid for diphtheria prevention Tetanus-Gas Gangrene Antitoxin for prophylaxis and Staphylococcus Toxoid for the prevention and control of staphylococcal infections

Their pharmaceuticals include Solution Liver Extract Parenteral for pernicious anemia Solution Liver Extract Oral Ferric Ammonium Citrate in capsules Cod Liver Oil Concentrate Tablets and standardized Whole Leaf Digitalis Tablets

- 10—Winthrop Chemical Company, Inc, and H A Metz Laboratories, Inc, 170 Varick Street, New York, New York

At the Winthrop-Metz booth you will find a special exhibit of some of the newest products

of this firm Special attention is called to Novaldin the analgesic with a wide safety quotient Myorgal, vasodilator for angina, Synodal, for injection therapy of peptic ulcer, Diadrast, radiopaque agent for intravenous urography Literature gladly supplied on these, as well as Curtasal, Avertin, Luminal, Theominal, Phanodorn, Pyramidon Novocain, Salyrgan, Omnadin and the Salvarsans

11—Gerber Products Company, Fremont, Michigan

Any information desired concerning the Gerbers Strained Cereal, Vegetables and Prunes will be gladly given Leaflets and booklets are available for use in your practice or for your own information Gerber Products are used both for infant feeding and in therapeutic diets and literature along those lines will be supplied.

12—Petrolagar Laboratories, 8134 McCormick Blvd, Chicago, Illinois

Each tablespoonful of this new type of Petro-lagar contains the physiological equivalent of the U S P dose (2 cc) Fluid extract Cascara Sagrada U S P There is a sample of Petro-lagar with Cascara for every visitor

13—Massachusetts State Pharmaceutical Association, 20 Glen Road, Newton Centre, Massachusetts

A line of U S Pharmacopoeial and National Formulary preparations will be displayed

14—R B Davis Company, Hoboken, New Jersey

Cocomalt, the scientific food concentrate that supplies a rich calcium, phosphorus and Vitamin D content in a delicious form, is again being exhibited Physicians report an ever-increasing use of Cocomalt in the diet. Interesting scientific data available Scientific information will be given and questions on Cocomalt will be answered

15, 16—Merck & Co, Inc, Rahway, New Jersey

Manufacturers of fine prescription chemicals In addition to such well known therapeutic agents as Tryparsamide, Bismosol, Stovarsol, and Pyridium, several interesting new preparations such as Mecholin, for the treatment of paroxysmal tachycardia and peripheral vascular diseases will be exhibited

17—Physician-Dentist Service, Inc, 224-225 Park Square Building, Boston, Massachusetts

Finances the patient for the doctor or hospital A complete explanation of their plan will be available J R Watson, Assistant Treasurer, will be in charge

18—The DeVilbiss Company, Toledo, Ohio

Manufacturers of medicinal atomizers and vaporizers A complete line of medicinal atomizers and vaporizers will be on exhibit. A prominent feature of this display will be the new DeVilbiss Nasal Guard, which eliminates any excess pressure in the nasal passages during prescribed self treatment with an atomizer E Manning of the Boston Office will be in charge

19—Crosbie-Macdonald Insurance Agency, 79 Milk Street, Boston, Massachusetts

Specializing in protection for members of the Massachusetts Medical Society, against reputation, good name, working ability, instruments your life and retirement can be provided for They will be glad to help solve your problems

20—Moore & Company, Inc, Worcester, Massachusetts

21—S M A Corporation, Cleveland, Ohio

22—Hynson, Westcott & Dunning, Charles and Chase Streets, Baltimore, Maryland.

23—Campbell X-Ray Co of Boston, 100 Sudbury Street, Boston, Massachusetts

X ray and electro-medical apparatus made in Boston will be displayed

24—Mead Johnson & Company, Evansville, Indiana

A complete line of infant diet materials including Dextrin Maltose Meads Newfoundland Cod Liver Oil, Meads Viosterol in Oil 250 D, Meads 10 D Cod Liver Oil Meads (A D) Viosterol in Halibut Liver Oil 250 D (Liquid and Capsules), Meads Halibut Liver Oil Meads Brewers Yeast Powder, Meads Brewers Yeast Tablets Pabulum, Meads Cereal, Sobee, Meads Powdered Protein Milk, Meads Powdered Lactic Acid Milk, Powdered Whole Milk Alacta, Reolac and Casco will be displayed

26—The Mellin's Food Company, 177 State Street, Boston, Massachusetts Manufacturers of Mellin's Food

27—Charles W Broadbent Company, 665 Huntington Avenue, Boston, Massachusetts

A complete line of Medical, Surgical and Hospital Supplies will be displayed Charles W Broadbent will be in charge

28, 29—E F Mahady Company, 851-857 Boylston Street, Boston, Massachusetts

The new Burdick SU2 Endo-thermic Knife utilizing a blended current comprising patented cutting and coagulating features will be displayed Also the new Baxter's Intravenous Solutions, the Sciolytic Flash emergency and operating light, and many other new items of interest to the medical profession

30—Horlick's Malted Milk Corporation, Racine, Wisconsin

Manufacturers of Horlick's the Original Malted Milk. A complete line of Horlick's the Original Malted Milk, powder and tablet forms natural and chocolate flavors will be displayed. Dr J A Denking of Boston will be in charge

31—Association of Certified Milk Producers of Metropolitan Boston, 1106 Boylston Street, Boston, Massachusetts

The methods and technical control procedures pursued in the production of Certified Milk will be presented Certified Milk is produced under medical supervision to fulfill the most exacting requirements of the medical profession for clean, safe milk of optimum nutritional values

32—Davies, Rose & Co, Ltd, 22 Thayer Street, Boston, Massachusetts

While Pili Digitals (Davies Rose) needs no introduction, there are perhaps those who are

not familiar with this firm's other preparations Messrs Mansfield and Fleming will be in charge

33—The E L Patch Company, Stoneham Post Office, Boston Massachusetts

The various Patch specialties will be displayed

Booths A and B—The Stetson Shoe Company, South Weymouth, Massachusetts

Manufacturers of high grade shoes for men and women A complete line of Stetson Shoes will be displayed. C C Mason will be in charge

Booth C—The J B Lippincott Company, Philadelphia, Pennsylvania

The J B Lippincott Company will exhibit an unusual line of new and standard medical surgical pharmaceutical and nursing books Among the most outstanding is Peham and Amreich—'Operative Gynecology,' in two volumes This atlas is beautifully and extensively illustrated by large drawings showing each operation step by step Practically all of them are beautifully and accurately colored

Kirschner—Operative Surgery, in two vol

umes This book immediately became known as 'The Color Surgery' because of the wealth of detailed colored illustrations It contains a great number of items that cannot be found in any other Operative Surgery and is well worth the most careful scrutiny

There is a new edition of the well known doctor's time saver, Lippincott's Quick Reference Book and an entirely new and most inexpensive work on 'The Treatment of the Commoner Diseases' by Lewellys F Barker, and the new idea in personal post graduate work instruction at home supplied from the Pittsburgh Diagnostic Clinic as a Supplement to the famous International Clinics

In the nursing field there is an entirely new work by Solomon on 'Pharmacology, Materia Medica and Therapeutics for Nurses' and a number of new editions of the standard nursing text

TUFTS ALUMNI LUNCHEON

A Tufts Medical Alumni luncheon is scheduled for Monday, June 4th, at 12 30 P.M. at the Hotel Bancroft, Worcester

Careful perusal by the Fellows of the Society of the program set forth should arouse that degree of enthusiasm which would prompt designation in one's engagement book of the three days of the Annual Meeting Every section is well arranged to present important educational material, and the accepted estimate of a practitioner is based on his attendance at medical meetings

Last year the scientific exhibit was unanimously approved as a very interesting and instructive feature of the session That arranged for the Worcester meeting presents significant advancements in medicine The commercial exhibits should interest every doctor, for the best pharmaceutical skill is shown in the various products displayed, and the mechanical and scientific contributions to a doctor's armamentarium are examples of the ingenuity of the manufacturers Cordial invitations are extended to visit these exhibits

The most valuable vacation period for the summer will be that at Worcester June 4, 5, and 6

Do not miss the Annual Dinner, for the social features are important adjuncts to scientific meetings Your President will be especially pleased to see you there, for thereby you may show your appreciation of his devotion to your interests He has secured speakers who will entertain you

The general and local committees have worked diligently to provide for your entertainment

Read the program carefully a second time and mark those features which you find therein of interest

NEW ENGLAND SURGICAL SOCIETY

COMPRESSION FRACTURES OF VERTEBRAL BODIES*

BY JOHN P. BOWLER, M.D.,† AND JOHN F. GILE, M.D.†

COMPRESSION fractures of vertebral bodies are not an uncommon result of accidents in the fields of both recreation and industry. The work of Osgood and Rogers here in Boston, preceded by that of Brackett, Mixter and Wilson, and Sever, as well as by Cotton's earlier report of a case, should be sufficient reason for not bringing this discussion to the particular location of this meeting. But, based on our own experience, we believe that the practical importance of a discussion of compression fractures still lies in the frequency of failure of their early recognition, particularly when so commonly unaccompanied by signs of cord involvement. Complicating as they may an apparently trivial and not seriously disabling injury, the early symptoms may be ascribed to "back sprain", "muscle pull", "lumbago", and excite in either the patient or physician or both, no indication or perhaps justification for complete roentgenologic investigation, without which the diagnosis cannot be made. The delayed recognition forced by the continued or progressive development of symptoms results in diagnosis at a time when later pathological changes have rendered an originally simple problem less amenable to treatment.

This introduction well describes our own experience. Not many years ago we experienced the discomfiture of having a late diagnosis of compressed fracture established on a case dismissed by us as back sprain. In 1932 we treated nine cases of compressed fracture, which raised the question of the increasing prevalence of the condition and caused a review of our hospital cases dismissed with diagnosis of back sprain. Of twenty-two such records, nineteen included sufficient x-ray data to indicate a correct classification so far as exclusion of fracture was concerned. In three cases, however, there was definite history of injury of a type and sufficiency to have caused fracture, the disability could have accompanied fracture, x-rays were not taken, and strapping of the back constituted treatment. The fact that these three cases have not returned to us may or may not support the hope that the diagnosis was correct.

The mechanism involved in compression fractures is determined by the structure and motions of the spinal column which functions as two segments: the superior long flexible portion supporting the head and carrying the tho-

rax and abdomen and the inferior or short rigid portion carrying the lower extremities. The spinal column is comprised of superimposed vertebrae bound together by strong ligaments and held in alignment by strong active musculature. It is important to recall here that the posterior or lamina ligaments as their name, *ligamenta flava*, implies, are yellow, elastic tissue which gives more and more under tension, does not tend to rupture—that they are not fibrous check ligaments as in the normal joint anatomy. The vertebrae articulate anteriorly through their bodies by the interposition of fibrocartilaginous disks and posterolaterally through articular processes. Movements exceeding the wide normal range unduly compress the vertebral disks or cause fracture of related bodies. Each vertebra consists of an anterior mass of spongy bone, the body, and a strong posterior portion, the neural arch.

The normal curvatures of the spine, responsible for the extreme elasticity of the column, result from the shape of the vertebral bodies as well as that of the intervertebral disks, both of which are thicker on the convex side of a curvature, and best developed in those regions of greatest flexibility of movement. In general, the greatest mobility occurs where normal flexion is the greatest, as in the cervical and lumbar regions. In the lumbar segment, due to the relative fixation both above and below and the immense leverage of the trunk working against the pelvis, occurs the great majority of compression fractures as a result of violent, exaggerated flexion. Such trauma is spent on the large cancellous vertebral body, resulting in a degree of compression commensurate with the force and the absence of subluxation or dislocation as a means of escape. Complete escape, meaning dislocation without fracture, is extremely rare, one interesting instance, followed by complete reduction, we shall show. The compression vice is maintained by the resistance of the strong neural arch and ligaments posteriorly and the common anterior ligament anteriorly.

Fractures of the spine are placed in two definite groups by the presence or absence of cord involvement resulting from the presence and extent of dislocation accompanying the fracture. Of forty-four cases of fractured spine treated by us in the past ten years thirty-six have been of the compression type involving one or more vertebral bodies. Of these thirty-six cases twenty-nine were of a simple compression type without sufficient dislocation or damaging complications to produce cord signs. In 1932, encoun-

*Read at the Annual Meeting of the New England Surgical Society September 30, 1932 at Boston.

tering nine such cases we were impressed with the correctness of the general belief that such fractures were rapidly increasing because of both the increasing prevalence of automobile accidents and the improved x-ray technique and facilities as offering less possibility of incorrect diagnosis. Our yearly incidence however does not indicate any unusual variation within the period under discussion. The incidence of these cases in our records ranges from three to six cases each year, increasing to six in 1926 and to nine in 1932. Of the ten-year total of forty-four twenty-five cases have occurred in the last five years.

The seven cases complicated by dislocation are the only cases in which there was cord involvement. This varied from paresthesias of one lower extremity in one case to complete paraplegia in six cases with varying degrees of recovery, and with two deaths. Probably of no particular significance these two deaths to which our fatalities were confined followed fracture dislocation of the eleventh dorsal vertebra, in one of which autopsy showed death from pulmonary embolus one week after injury and in the other puncture of the hemiazygos vein by the fractured vertebra and rupture of the liver. In these seven cases, fracture was confined to a single vertebra in four, multiple vertebrae were involved in three. Not included in our list of spinal fractures but of interest to report in connection with the mechanics of spinal injuries is one case of complete dislocation of the spine without fracture. Herzkooff of Los Angeles in discussing such a case states that after a careful review of the literature he found no other case reported. We should like to report a complete anterior dislocation of the spine without fracture occurring at the twelfth dorsal vertebra with overriding downward over the bodies of the first and second lumbar vertebrae. The patient was a man of forty-eight years of age, injured in an automobile accident. X-rays taken one year after injury show a complete reduction. The patient is now living, five years after injury, with a complete paraplegia.

We have mentioned these cases associated with dislocation as a result of a more extensive action of the force causing the spinal injuries. This reduces our report to twenty-nine cases of uncomplicated compression fractures of the vertebral body with no cord involvement and with which associated injuries are rare. In the case of the patient in shock or with paraplegia there is not much likelihood of an atmosphere of trivial injury and casual management.

Automobile accidents have been credited as the origin of the increasing prevalence of compression fractures. A list of injuries involving violent hyperflexion is, in our experience led by falls from trees, staging, etc., resulting either in the individual's landing feet first in a position of flexion of the trunk or falling across a raised object. Of our thirty-six cases eighteen, or just

one half, resulted from such falls, eight, or less than one fourth from automobile or train accidents, four were caused by a blow on the back with heavy pressure and occurring in logging accidents, three from tobogganing, and three of miscellaneous origin. Those resulting from tobogganing could easily be overlooked. In passing the case mentioned earlier as not diagnosed by us occurred from this very cause. There was no accident collision or "spill." The compression resulted from hyperflexion on the rebound from a not-unusual bump with the patient sitting on the toboggan with thighs flexed and knees extended an ideal set-up for such an injury if once considered. Oddly enough we have yet to encounter our first case resulting from skiing—but not strange when one recalls the mechanics of the injuring force and the fact that flexion is the position of an efficient skier and that most falls are backwards or sideways in a position of spinal extension.

The location and extent of the fracture in these thirty-six cases are of considerable interest from the standpoint of the mechanics of the

injury and because of the relationship of multiple fractures to the site. Of the thirty-six cases twenty-seven involved but one vertebral body with the inclusion of each vertebra from the eleventh dorsal to the fifth lumbar, inclusive, and with the involvement of the eighth dorsal in one instance. Of these twenty-seven cases twenty-one or seventy-seven per cent occurred in the lumbar spine, the second lumbar leading with fracture in seven cases. Six single fractures of one body were confined to the dorsal region, the body of the eleventh leading with four. In the cases of multiple fractures, of which there were nine the extent was from the fifth dorsal to the fifth lumbar. In those cases there was involvement of two to four bodies. In all but four the fractures concerned contiguous vertebrae, the escaping vertebrae between the two segments of fracture varying from two to six in number. The above table gives

the incidence of fracture as occurring in the various bodies

The age and sex incidence of these patients is of no significance, occurring with the same incidence as in general traumatic cases, twenty-five per cent were in women, and the ages of the entire group varied from fifteen to eighty-one.

To return to our twenty-nine cases of simple compression fracture without cord involvement, the diagnostic symptoms are not definitely pathognomonic of fracture. The constant symptoms are tenderness in the back, usually well localized over the spinous processes of involved vertebrae, and pain which usually follows immediately after injury and is continuous until a corrective position is maintained. The pain is located in the general region of the tenderness and may be girdle-like in character. There may be swelling at either side of the site of fracture. Kyphosis in the early and uncomplicated case is not present. The diagnosis is possible only by x-ray and the important issue in arriving at the diagnosis is a history of the manner of injury, a recollection of the mechanics of its production, a definite insistence with the patient of the possibility of the condition without further symptoms, and an insistence on complete roentgenological investigation.

The interval after injury which has occurred before some cases have been seen is significant of the casualness with which both physician and patient may regard a lame back following injury. Nineteen of our cases were seen within twenty-four hours. In thirteen the time averaged two and one half weeks, and in the four remaining, this interval was three months, seven months, eighteen months, and four years. These late cases had been treated with a short period of rest in bed, strapping, and finally came in with a complaint of persisting backache. The position of comfort in these injuries is moderate flexion and absence of lordosis, and is to be kept in mind in suspecting the diagnosis and in considering the transportation of such a patient.

The treatment obviously reverses the mechanics of the injury, and consists of hyperextension, for which many devices, tables, and maneuvers have been utilized. As a result of the muscle spasm which is present in the early cases immediate extension involves considerable traction on the abdominal muscles resulting in pain and extreme discomfort, often followed by nausea, vomiting, and, at times by distention which may become serious. If extension is accomplished in a gradual manner, much of this discomfort can be avoided. The placing of sandbags and built-up slats under the patient has been one practical method for the institution of this extension. Except in the case seen immediately after injury we have found the early application of a cast to be often unsuccessful usually producing such a degree

of discomfort as to force its discontinuance. We have found the simplest method of producing gradual extension to consist of reversing the patient, head for foot, on a standard Gatch bed and using the knee elevator as a pressure producing extension of the spine, this mechanism lends itself very well to gradual application. We have extended the use of this method to a period of from ten to fourteen days, at which time all spasm has disappeared. The patient is then put on the ordinary Bradford frame in a canvas hammock and a body cast is applied with the spine in satisfactory hyperextension, taking care that padding in the region of the injury is sufficient to prevent undesired pressure over the area of fracture and to maintain extension later when the cast may be less well-fitting. Such casts are worn from ten to twelve weeks with the patient ambulatory after the sixth or eighth week. On removal of the cast a Taylor brace is applied, which is worn for the balance of one year following injury, during the last six months of which the patient can usually return to ordinary work. We realize that there is a considerable difference of opinion as to the length of time that a patient should be immobilized with such an injury. In spite of some proponents of a much shorter period of immobilization, we feel safer on the program as stated. In the cases complicated by dislocation, with the early period of hyperextension has been combined leg or head traction or both as indicated. In general we have found the higher the fracture in the spinal column the more difficult the satisfactory reduction.

It would seem that no discussion of this type of fracture would be complete without reference to Kuemmel's disease. A considerable amount of literature on this entity has accumulated since Kuemmel's first article in 1891. It must be borne in mind that Kuemmel's articles preceded the practical use of the x-ray. The following sequence of events was described as necessary to make such a diagnosis:

- 1 Injury to the spine
- 2 Period of disability
- 3 Latent period
- 4 Recurrence of pain and disability due to crushing of a vertebral body
- 5 Arrest of the process by proper treatment

In other words, to establish a diagnosis of Kuemmel's disease, an x-ray must be taken immediately after injury and found negative, and the patient later develops the subsequent course of events. Bahn believes there is a microscopic dissolution of the continuity of the bone, which, without treatment, degenerates, absorbs, and collapses. Jones of Liverpool believes the fracture is reduced by manipulation of moving and therefore does not show, but without proper treatment crushes under the body weight and

the ensuing events occur. There seems to be but little doubt that so-called Kuemmell's disease is the late result of an unrecognized and therefore untreated crushing of the vertebral body.

CONCLUSION

1 Our cases of compression fracture of vertebral bodies without dislocation have been accompanied by no signs of cord involvement.

2 Such fractures resulting as they may from an apparently trivial injury may escape early recognition.

3 Kuemmell's disease is the late result of an unrecognized and therefore untreated case of such fracture.

DISCUSSION

DR. EZRA A. JONES Manchester N H. *Mr President and Gentlemen*—There are two points that are brought out in this paper which are extremely interesting to me. One is the failure to make a diagnosis in cases of compression fractures without cord involvement and the other is the recovery of these patients without any fixation operation.

I think the failure to make a diagnosis is due to two factors. First the failure to get a definite history as to how the accident occurred and the second is the inadequate x-ray examination. Compression fractures always occur with the spine in flexion and if it is found that flexion of the spine could have occurred during the accident we should be suspicious of a compression fracture. Slight compression fractures can seldom be diagnosed in an anteroposterior x-ray and lateral views should always be taken.

The use of the Rogers' bed makes the treatment very simple but if that cannot be had hyperextension can be made with a blanket roll placed under the point of fracture. I have been using for several years the Whitman frame which I believe has many advantages. It is inexpensive, mobile and quite effective. It can be made by any plumber and consists of a heavy gas pipe about six to eight inches longer than the patient and as wide as the patient's shoulders at either end. It is curved upward from the bed to any degree desired and at the point where pressure is desired the pipes are placed to within two inches of each other for about four to five inches at the point where the fracture occurred. The effectiveness of this is that the

pressure comes on the transverse processes and not on the spinous processes. While on this frame, x-ray may be taken and any desired amount of hyperextension may be secured. After four weeks in this position a plaster corset is applied and this is worn for about four months when a back brace is instituted. It is rare to find a case treated this way which does not go on to recovery.

DR. JAMES W. SEVER Boston Mass. I am very much interested in this matter of compression fractures of the spine because a number of years ago when I was doing more industrial surgery than now, I picked up a great many which had been unrecognized and untreated. I was not the first nor the only one but I missed many. My imagination wasn't sufficiently good at that time to visualize what should be done for them and I was content to treat these cases with some support or perhaps do something along the lines they had been having or give them more treatment than they needed or had had.

It remained for others with a better visualization of the problem to sense that hyperextension was the thing that was really needed particularly in the acute cases and you of course are familiar with Danlo's method of forcible correction and later Daviss (in Erie) under an anesthetic with immediate correction of the wedging of the body and later the excellent work that William Rogers has done with his fracture frame as it is called. Since we have been shown the path that we should take with those cases the problem has not been a particularly difficult one so far as correction of the deformity goes.

It is perfectly amazing to see how the accordion will open with hyperextension properly applied and with restoration in many cases to complete symmetry and anatomical outlines of the injured body particularly of course in the lumbar region.

The medical profession so far as the pathology of the spine has gone has made more advances in the last five or ten years than have ever been made so far as I know. In the old days of railroad spines, or contusions of the spine before x-rays people were content to go on perhaps with traumatic neurosis or lame back and nobody thought much about it. Perhaps Kuemmell's disease was more frequent than it is now and I think most of Kuemmell's works were written before the advent of the x-ray, so perhaps he couldn't tell that there had been a primary injury to a body of the vertebra.

The early treatment as we followed it and as I think Dr. Gile has said should be hyperextension but hyperextension immediately applied is peculiarly uncomfortable and distressing and oftentimes leads to rather grave symptoms. Many of these people have a good deal of abdominal distention which is disturbing because you don't know whether they have an intestinal or a bladder rupture, and in those cases they will not stand a hyperextension at all. Even after that condition has quieted down forcible hyperextension applied may bring back symptoms which are extremely uncomfortable and painful.

In the old days when a person had a fractured back everybody knew it and when the diagnosis was made of fractured spine a person was immediately permanently incapacitated. The injury was associated with a section of the cord, dislocation of the cord and paraplegia and with symptoms which persisted because of the cord injury. The term

fractured back today except in the terms of psychology is not particularly a serious condition. With the x-ray you can see compression fractures of the vertebrae or those fractures which Dr. Gile has shown which should not be called compression fractures so much as sprain fractures where corners are pulled off and where there is no frank compression of the body itself.

Today a fractured back simply means that there is a fractured lamina, or a pedicle, or a transverse process, or a sprain fracture of a corner. Even a fracture of the vertebral body doesn't mean prolonged illness or disability, and the reason is not only because of the x-ray studies but also of the sense with which these problems have been met in terms of treatment.

There is one other thing which I should like to speak of and that is in the older people, who have marked hypertrophic arthritis, and who have injuries to the back from falls, from stagings from roofs from wagons, or whatnot. I have been unfortunate enough to make a diagnosis in several of these cases where there has been severe accompanying hypertrophic arthritis of the spine in compression fracture—there are severe distortions and asymmetrical conditions of the vertebral bodies which on top of a severe injury to the back, are mistaken even by the x-ray man as a compression fracture, and on review of the case the diagnosis has to be changed to "aggravated by hypertrophic arthritis" as the Compensation Commissioners like to say.

I have here something devised by one of the orderlies at the Boston City Hospital. It is an arrangement of a flexible steel plate. It is put under the patient and there is a ratchet arrangement here, that can be gradually turned up. I think it is known as the "City Hospital Hyperextension frame." The felt pad can be removed or padded, as you choose. Every day the plate can be turned up a bit, increasing hyperextension which is a better way than to do an immediate forcible correction. The apex of this plate should be under the deformity, and it can be readily and easily adjusted without discomfort to the patient. With this apparatus we can have hyperextension without danger of abdominal disturbance to the point where the x-ray shows an excellent restoration of symmetry of the compressed vertebrae.

DR ROBERT B OSGOOD Boston Mass. I think that this is the most refreshing paper on compression fractures of the spine to which I have ever listened. It has an enormous amount of common sense in it and practical simple methods of dealing with such lesions. It emphasizes the one important thing in relation to accidents to the spine, namely, that suspicion is the key that opens the door to diagnosis. We must think of this possibility always in injuries of the back, especially when we do not know the exact mechanism of the accident. This is very frequently the case.

It is refreshing particularly because not one word has been said about fusion operations for compression fractures of the spine and I think it should rarely be said because it is obviously not necessary in the cases dealt with properly soon after the injury.

I think Dr Sever is wrong. Dr Davis gave the first clear exhibition of what could be done by manipulation. Dr Dunlop and many other people have advised hyperextension. Dr Davis deserves the credit of first demonstrating the possibility of opening up as Dr Sever so well called it, the accordion.

There is one thing I should like to bring out very

definitely in this connection and this is that in the older cases it is very common after the diagnosis has been made, to advise a fusion operation because of disability and pain. If you study these cases carefully, you will find that a certain proportion of them have a perfectly good internal fixation by nature (drawing on the board) something like 33 per cent as I remember it of a large number of cases reported in St. Louis. The fusion operation would not then need to be done for the sake of fixing this region, because it is already fixed and yet these cases often have pain and discomfort. The reason they have discomfort, as Wallace has well shown is the fact of the postural defect in the spine caused by the wedge shaped vertebra and the discomfort does not come from the fracture, but from the disturbed posture.

You may in the older cases, without doing a fusion operation, certainly always before you do a fusion (as you may be obliged to do in workingmen) produce by hyperextension compensatory curves above and below the seat of the fracture in the spine which will reduce the postural defect and relieve the pain without any operative procedure.

I happen to have had to deal with a great many of the older cases where the lesion has been unrecognized and a correction of the postural defect by means of compensatory curves above and below has entirely relieved all symptoms without a fusion operation.

I think Dr Gile and Dr Bowler are to be warmly commended for the whole attitude of the paper and for the points that they have so well brought out.

DR JAMES W SEVER. May I ask Dr Gile a question? I should like to ask in relation to the border line cases in compression fractures where there has been a frank compression fracture of the body and where there are at first and oftentimes persisting for some time, certain neurological symptoms in the legs whether it is advisable in those cases, early or late, to do a laminectomy.

DR JOHN F GILE. I said nothing about the fusion operation because I don't know anything about it in the first place never having done one and we haven't found the necessity for doing it. By correcting putting on a proper brace or a cast, even in the old cases you get relief, so I have found no occasion for using it.

The suspicion of a flexion accident was brought out by Dr Osgood in an article some years ago and is more or less the basis of our repeating it here. The suspicion of it is the thing to keep in mind. Suspect that there was a flexion and you have an idea of what may have happened.

Since this paper was written a patient last week came to the x-ray man with a diagnosis from a doctor of some internal disease around the cecum and wanted a barium enema. Dr Sycamore, with the story of the man's having had a fall last March took an x-ray and found nearly complete compression fracture of the vertebrae.

We have not done laminectomies in these cases. With complete paraplegia we have felt that we would do no good—perhaps more radical treatment is indicated. The paraplegias and slight neurological symptoms have cleared up with traction.

THE NECESSARY REQUIREMENTS IN A MINIMUM
DIET FOR INFANTS AND CHILDREN

BY JOHN LOVETT MORSE, M.D.*

AT this time when so many children are underfed and undernourished and when it is also so important that they be properly fed at as low a cost as possible, it seems worth while to review briefly what their nutritive needs are and how they can be met.

The minimum diet must contain proteins, fats, carbohydrates, salts and vitamins and must also provide the requisite number of calories. Its bulk must also be taken into consideration. Attention must likewise be paid to its palatability and digestibility points which are unfortunately frequently overlooked or forgotten. The relative importance of the caloric value of foods was undoubtedly overestimated in the past. Absolutely, however, it is as important as it ever was. The importance of the vitamins is now being relatively very much overemphasized although, of course, no diet is complete which does not contain a sufficient amount of them. They are really no more important and necessary than certain amino-acids or even common salt, which are seldom mentioned.

It is stated in the reports of The White House Conference that "the correct procedure in constructing a diet must consist in first attempting to provide a complete assortment of the substances which sustain the chemical structure of the body and then adding combustible material in such amounts as will provide the necessary energy." This statement is undoubtedly true. Nevertheless, I am going to follow the custom, usual in the past, of taking up the caloric needs first, and considering the other needs later.

CALORIC NEEDS These, in brief, consist of (1) The basal metabolic needs, which gradually diminish with age and, measured in body weight, are less in the fat than in the thin. (2) The needs for growth, which are greatest in infancy and in the prepubertal period. (3) The needs for muscular activity, which must necessarily vary enormously. (4) The needs for waste which are relatively unimportant. It is evident how difficult it is to estimate these needs even to get average figures. It is far more difficult to estimate them for the individual.

Most tables merely approximate what their makers think children ought to take and are consequently not of great value. Those which are based on what well, growing children actually eat are probably more nearly correct. Figures based on weight are probably less accurate than those based on height. According to the findings of The White House Conference, the caloric

needs of boys gradually increase from thirty-five calories per inch at two years to fifty-five at seventeen years, while the needs of girls vary from thirty-nine to forty from six to fifteen years and between thirty-five and thirty-seven before and after this time. Approximate average figures as to the caloric needs of infants and children, based on those given by The White House Conference are as follows:

Infants Sex has no influence

1 month	500	Calories
6 months	800	"
1 year	1000	"
2 years	1200	"

Children	Boys	Girls
2-3 years	1200	1225
4-5 "	1525	1450
9-10 "	2250	2000
11-12 "	2325	2175
13-14 "	2625	2400
14-15 "	2900	2375

The figures given by Holt and Fales, modified by my own experience, are, I think, more nearly correct for children of twelve years or over. These are, for boys of twelve years, 2750 C, and for girls of the same age, 2950 C, at fifteen years, boys, 3750, and girls, 3700.

Finally, it must always be remembered, as stated in the proceedings of The White House Conference, that "each individual child has his own caloric needs which may vary from that of others of the same age and size. This optimum is such that the child grows properly, feels well, is mentally and physically alert and adjusts himself to his environment. Standards of food intake are of value in improving the welfare of children, but should not be used to the exclusion of the consideration of the problem of the individual child."

PROTEINS As is well known, protein is the only one of the food elements from which old tissues can be replaced and new tissues built. No diet is adequate which does not contain enough protein to do this. Furthermore, the supply must be continuous, because proteins—i.e., amino-acids—are not retained in excess of the immediate requirements. The proteins are changed into the amino acids before they are absorbed. Most of these amino acids are interchangeable, but at least four of them are not. These are tryptophane, lysine, cystine and histidine. They cannot be synthesized in the body but must be taken in the food. Fortunately there is very little chance of an insufficiency of any of them, unless barely possibly of cystine, if a baby is on the breast or a baby or child is drinking milk. Practically, it is not necessary to consider them. Incidentally, on the whole,

Morse, John L.—Consulting Physician Children's Hospital, Infants Hospital and Beth Israel Hospital. For record and address of author see "This Week's Issue" page 1053.

animal foods provide a better selection of amino-acids than do vegetable

The storage of protein for growth will be defective on diets which do not contain sufficient calories, as some of the protein will be burned for energy. Proteins may yield glucose, fatty acids and fat. As much as fifty per cent may be converted to glucose. Protein is a wasteful source of energy. This is shown by a comparison of the specific dynamic action, i.e., the "cost of digestion", of the various food elements, which is 25 per cent of the fuel value of fat, five per cent of that of the carbohydrates and ten per cent of that of the proteins.

The minimum protein need is the minimum amount of protein required to replace used tissues, build new, and pay the cost of digestion, assuming that the diet is otherwise sufficient, so that protein does not have to be used as fuel. The figures as to the minimum protein needs are probably more accurate for infants than for children. The breast-fed baby gets from 18 grams to 23 grams of protein per kilogram of body weight daily. This is equal to from seven to nine per cent of his total caloric intake. Various studies seem to show, however, that 15 grams per kilogram are enough. Babies taking the modern whole milk mixtures get from 26 grams to 58 grams of protein per kilogram, or from twelve to twenty per cent of their total caloric intake. This is probably too much, as has already been explained.

The figures as to the protein needs of children are conflicting and probably not very reliable. Holt and Fales found that from six years on, healthy, growing children took about 26 grams per kilogram. Various figures, which I have analyzed, seem to show protein needs of 35 grams per kilogram at four years, 25 grams at eight years, and two grams at twelve years. These amounts are probably larger than necessary. Other estimates are that from one to five years ten to fifteen per cent of the total calories should be provided by proteins, and in older children, five to ten per cent.

The chief symptom of protein insufficiency is failure to grow properly. If there is a marked insufficiency, nutritional edema may develop. In such cases, however, it is often very difficult to know how much of the edema is due to the protein insufficiency and how much to an excess of the other food elements and to a deficiency of vitamins, both of which are usually associated with an insufficiency of proteins. There are no pathognomonic symptoms of an excess of proteins. It is intriguing to think that an excess may injure the liver and kidneys, but, so far as I know, there is no proof that it does. Almost all that can be said is that proteins are an uneconomical source of energy, and that, therefore, it is wasteful to use them for this purpose.

CARBOHYDRATES The carbohydrates comprise the sugars and starches. Both must be broken down into monosaccharides before they can be absorbed. It must not be forgotten in this connection that raw starch is digested with much difficulty because of the indigestibility of the cellulose which surrounds the starch granules. Starch which is not broken down cannot, of course, be absorbed and, therefore, cannot be utilized. All the carbohydrates serve the same purpose in nutrition. This is mainly as a source of energy. Nevertheless, a certain amount of carbohydrate is necessary for the maintenance of life and to prevent ketosis. This minimal need is three grams per kilogram of body weight for infants and from eight to ten grams for children. The amount of carbohydrates needed to supply energy depends somewhat on the amount of fat in the food, which also serves mainly as a source of energy. Within reasonable limits they can be used indiscriminately for this purpose. In a general way, everyone agrees that the optimal amount of carbohydrates for the infant is from ten to fourteen grams per kilogram of body weight and from eight to ten grams for children. This means from forty to sixty per cent of the total caloric intake.

Carbohydrate insufficiency never occurs except in starvation. An excess of carbohydrate in the diet is, however, probably the most common mistake made in feeding children. The usual symptoms are indigestion and loss of appetite, if there is a great excess, glycosuria. There are no characteristic symptoms of an excess of carbohydrates. Those which are often attributed to it are really due to an insufficiency of the other food elements, especially of protein, and a deficiency of salts and vitamins.

FATS The fats serve mainly as a source of energy. Some form of fat, however, enters into the composition of every cell of the body. A certain amount is, therefore, necessary for the maintenance of life and the building of tissue. There are no figures as to what this amount is. Fat is stored. If necessary, it can be synthesized from carbohydrate and protein. The caloric value of fat, by weight, is the highest of the food elements—93 vs 41 calories per gram. It has the lowest "cost of digestion". The normal breast-fed baby gets from four to six grams of fat per kilogram of body weight daily, or fifty per cent of its total calories. A baby on the modern whole milk mixtures gets only fifteen to thirty per cent of its total calories as fat. This seems to me to be too little. Children on an ordinary diet take from three and one half to four grams of fat per kilogram of body weight, or about thirty-five per cent of their total calories. No one knows whether this is optimal or not. Much more than this is probably not fully utilizable and quite probably interferes with the utilization of calcium. Many of the fats are also

important because they are carriers of vitamins A and D

The symptoms of fat insufficiency are not very definite. In the main, they are simply those due to an insufficient caloric intake. Except in starvation it is very improbable that not enough fat would be taken to carry on the vital processes. The symptoms which are usually attributed to an insufficiency of fat are really due to an insufficiency of the vitamins which are carried by the fats, namely, vitamins A and D.

Finally, to sum up, the optimal diet for children appears to be one in which protein makes up from ten to fifteen per cent of the total caloric intake, carbohydrate from forty to sixty per cent and fat from thirty to thirty-five per cent. The cheapest diet which will meet the nutritive needs is one in which ten per cent of the total caloric intake is provided by protein, sixty per cent by carbohydrate and thirty per cent by fat.

VITAMINS These accessory food factors are unquestionably necessary for the maintenance of health and normal growth. Their absolute importance cannot be overemphasized. Their relative importance is, however, being stressed altogether too much, largely because of the marvelous advertising and high-pressure salesmanship of the manufacturers of foods and drugs who have taken advantage of one of the few opportunities to make good money in these hard times. We physicians have only ourselves to blame for being exploited. The general public cannot be blamed because they cannot be expected to understand what is going on. The mistake which is being made is in assuming that unless a great effort is made to give the vitamins, babies and children will get an insufficient amount. Another mistake which is being made is in attributing many symptoms to avitaminosis which are in reality due to something else. Children still have sore eyes from other causes than a lack of vitamin A, loss of appetite may be due to indigestion as well as to an insufficiency of B. In general, in spite of all that has been written to the contrary, and although I know that I shall be reviled for saying so, I still think that the average child in the average American family runs very little chance of dodging a sufficient supply of the vitamins. The case is of course, very different among the very poor and among those who eat a very one-sided diet. Babies on the present low fat mixtures may also perhaps get an insufficient supply of A and D, especially if they are kept indoors. Furthermore with the present-day methods of feeding, all babies that are not breast-fed are very likely to get an insufficient amount of C. It is very fortunate that an excess of the vitamins does no harm. If it did many of our babies and children would certainly be in a parlous state. The manifestations of a marked insufficiency of the various vitamins are now pretty well known.

What is needed is a better knowledge of the symptoms of a slight insufficiency.

Vitamin A An insufficiency of this vitamin causes a specific change in the epithelial tissues. Stratified epithelium is substituted for the normal in various parts of the body, notably in the respiratory, alimentary and genito-urinary tracts. It is argued that this change results in an increased susceptibility to infection. Theoretically, it should. The best controlled clinical studies, however, seem to show that it does not. It would seem as if it ought to cause some disturbance of normal function. Certain changes in the skin have been described in infancy. A marked insufficiency causes night blindness and xerophthalmia. Vitamin A is stored. The limit of the capacity to store is not easily reached.

The common sources of vitamin A are milk, butter, eggs, animal and fish oils, and the green vegetables. Cereals and muscle tissues contain but little. Lard, vegetable fats and oils do not contain it.

Vitamin B This vitamin is made up of a number of different factors. The two most important ones are known as B-1 and B-2, or G. B-1 is the antineuritic and G the antipellagric or antidermatitic. The whole subject of the subdivisions of B is most confusing.

A marked deficiency of B-1 causes beriberi. A moderate insufficiency is said to cause anorexia, hypertonicity, and impairment of growth. There is probably nothing specific about the impairment of growth. This is presumably simply the result of the diminished intake of food because of the loss of appetite. Much has been said recently about loss of appetite in infancy and childhood as a symptom of an insufficiency of vitamin B in the diet. I am inclined to think that in the vast majority of instances the loss of appetite is not due to an insufficiency of vitamin B but to some unrecognized disease, improper hygienic surroundings or care, or some disturbance of the digestion from some other defect in the diet. At any rate, I have never been able to restore the appetite by increasing the amount of vitamin B in the diet.

The principal sources of B-1 are whole grains, wheat germ, yeast, the glandular organs, and the yolk of egg. Other sources are tomatoes, raw cabbage, fresh spinach and the legumes. Milk contains relatively little.

Vitamin G (B2) A marked deficiency of G causes pellagra. A moderate deficiency results in various forms of dermatitis, and is said to cause loss of appetite and impairment of growth. What has been said as to loss of appetite and impairment of growth in relation to B-1 applies also to G.

The sources of vitamin G in order of efficiency are liver, yeast, meat, milk solids, egg yolk, and whole grains.

animal foods provide a better selection of amino-acids than do vegetable

The storage of protein for growth will be defective on diets which do not contain sufficient calories, as some of the protein will be burned for energy. Proteins may yield glucose, fatty acids and fat. As much as fifty per cent may be converted to glucose. Protein is a wasteful source of energy. This is shown by a comparison of the specific dynamic action, i.e., the "cost of digestion", of the various food elements, which is 25 per cent of the fuel value of fat, five per cent of that of the carbohydrates and ten per cent of that of the proteins.

The minimum protein need is the minimum amount of protein required to replace used tissues, build new, and pay the cost of digestion, assuming that the diet is otherwise sufficient, so that protein does not have to be used as fuel. The figures as to the minimum protein needs are probably more accurate for infants than for children. The breast-fed baby gets from 18 grams to 23 grams of protein per kilogram of body weight daily. This is equal to from seven to nine per cent of his total caloric intake. Various studies seem to show, however, that 15 grams per kilogram are enough. Babies taking the modern whole milk mixtures get from 26 grams to 58 grams of protein per kilogram, or from twelve to twenty per cent of their total caloric intake. This is probably too much, as has already been explained.

The figures as to the protein needs of children are conflicting and probably not very reliable. Holt and Fales found that from six years on, healthy, growing children took about 26 grams per kilogram. Various figures, which I have analyzed, seem to show protein needs of 35 grams per kilogram at four years, 25 grams at eight years, and two grams at twelve years. These amounts are probably larger than necessary. Other estimates are that from one to five years ten to fifteen per cent of the total calories should be provided by proteins, and in older children, five to ten per cent.

The chief symptom of protein insufficiency is failure to grow properly. If there is a marked insufficiency, nutritional edema may develop. In such cases, however, it is often very difficult to know how much of the edema is due to the protein insufficiency and how much to an excess of the other food elements and to a deficiency of vitamins, both of which are usually associated with an insufficiency of proteins. There are no pathognomonic symptoms of an excess of proteins. It is intriguing to think that an excess may injure the liver and kidneys, but, so far as I know, there is no proof that it does. Almost all that can be said is that proteins are an uneconomical source of energy, and that, therefore, it is wasteful to use them for this purpose.

CARBOHYDRATES The carbohydrates comprise the sugars and starches. Both must be broken down into monosaccharides before they can be absorbed. It must not be forgotten in this connection that raw starch is digested with much difficulty because of the indigestibility of the cellulose which surrounds the starch granules. Starch which is not broken down cannot, of course, be absorbed and, therefore, cannot be utilized. All the carbohydrates serve the same purpose in nutrition. This is mainly as a source of energy. Nevertheless, a certain amount of carbohydrate is necessary for the maintenance of life and to prevent ketosis. This minimal need is three grams per kilogram of body weight for infants and from eight to ten grams for children. The amount of carbohydrates needed to supply energy depends somewhat on the amount of fat in the food, which also serves mainly as a source of energy. Within reasonable limits they can be used indiscriminately for this purpose. In a general way, everyone agrees that the optimal amount of carbohydrates for the infant is from ten to fourteen grams per kilogram of body weight and from eight to ten grams for children. This means from forty to sixty per cent of the total caloric intake.

Carbohydrate insufficiency never occurs except in starvation. An excess of carbohydrate in the diet is, however, probably the most common mistake made in feeding children. The usual symptoms are indigestion and loss of appetite, if there is a great excess, glycosuria. There are no characteristic symptoms of an excess of carbohydrates. Those which are often attributed to it are really due to an insufficiency of the other food elements, especially of protein, and a deficiency of salts and vitamins.

FATS The fats serve mainly as a source of energy. Some form of fat, however, enters into the composition of every cell of the body. A certain amount is, therefore, necessary for the maintenance of life and the building of tissue. There are no figures as to what this amount is. Fat is stored. If necessary, it can be synthesized from carbohydrate and protein. The caloric value of fat, by weight, is the highest of the food elements—9.3 vs 4.1 calories per gram. It has the lowest "cost of digestion." The normal breast-fed baby gets from four to six grams of fat per kilogram of body weight daily, or fifty per cent of its total calories. A baby on the modern whole milk mixtures gets only fifteen to thirty per cent of its total calories as fat. This seems to me to be too little. Children on an ordinary diet take from three and one half to four grams of fat per kilogram of body weight, or about thirty-five per cent of their total calories. No one knows whether this is optimal or not. Much more than this is probably not fully utilizable and quite probably interferes with the utilization of calcium. Many of the fats are also

important because they are carriers of vitamins A and D

The symptoms of fat insufficiency are not very definite. In the main, they are simply those due to an insufficient caloric intake. Except in starvation it is very improbable that not enough fat would be taken to carry on the vital processes. The symptoms which are usually attributed to an insufficiency of fat are really due to an insufficiency of the vitamins which are carried by the fats, namely vitamins A and D.

Finally, to sum up, the optimal diet for children appears to be one in which protein makes up from ten to fifteen per cent of the total caloric intake, carbohydrate from forty to sixty per cent and fat from thirty to thirty-five per cent. The cheapest diet which will meet the nutritive needs is one in which ten per cent of the total caloric intake is provided by protein, sixty per cent by carbohydrate and thirty per cent by fat.

VITAMINS These accessory food factors are unquestionably necessary for the maintenance of health and normal growth. Their absolute importance cannot be overemphasized. Their relative importance is, however, being stressed altogether too much, largely because of the marvelous advertising and high-pressure salesmanship of the manufacturers of foods and drugs who have taken advantage of one of the few opportunities to make good money in these hard times. We physicians have only ourselves to blame for being exploited. The general public cannot be blamed because they cannot be expected to understand what is going on. The mistake which is being made is in assuming that unless a great effort is made to give the vitamins babies and children will get an insufficient amount. Another mistake which is being made is in attributing many symptoms to avitaminosis which are in reality due to something else. Children still have sore eyes from other causes than a lack of vitamin A, loss of appetite may be due to indigestion as well as to an insufficiency of B. In general, in spite of all that has been written to the contrary, and although I know that I shall be reviled for saying so, I still think that the average child in the average American family runs very little chance of dodging a sufficient supply of the vitamins. The case is of course, very different among the very poor and among those who eat a very one-sided diet. Babies on the present low fat mixtures may also perhaps get an insufficient supply of A and D, especially if they are kept indoors. Furthermore with the present-day methods of feeding, all babies that are not breast-fed are very likely to get an insufficient amount of C. It is very fortunate that an excess of the vitamins does no harm. If it did, many of our babies and children would certainly be in a parlous state. The manifestations of a marked insufficiency of the various vitamins are now pretty well known.

What is needed is a better knowledge of the symptoms of a slight insufficiency.

Vitamin A An insufficiency of this vitamin causes a specific change in the epithelial tissues. Stratified epithelium is substituted for the normal in various parts of the body, notably in the respiratory, alimentary and genito-urinary tracts. It is argued that this change results in an increased susceptibility to infection. Theoretically it should. The best controlled clinical studies, however, seem to show that it does not. It would seem as if it ought to cause some disturbance of normal function. Certain changes in the skin have been described in infancy. A marked insufficiency causes night blindness and xerophthalmia. Vitamin A is stored. The limit of the capacity to store is not easily reached.

The common sources of vitamin A are milk, butter, eggs, animal and fish oils, and the green vegetables. Cereals and muscle tissues contain but little. Lard, vegetable fats and oils do not contain it.

Vitamin B This vitamin is made up of a number of different factors. The two most important ones are known as B-1 and B-2, or G. B-1 is the antineuritic and G the antipellagric or antidermatitic. The whole subject of the subdivisions of B is most confusing.

A marked deficiency of B-1 causes beriberi. A moderate insufficiency is said to cause anorexia, hypertonicity, and impairment of growth. There is probably nothing specific about the impairment of growth. This is presumably simply the result of the diminished intake of food because of the loss of appetite. Much has been said recently about loss of appetite in infancy and childhood as a symptom of an insufficiency of vitamin B in the diet. I am inclined to think that in the vast majority of instances the loss of appetite is not due to an insufficiency of vitamin B but to some unrecognized disease, improper hygienic surroundings or care, or some disturbance of the digestion from some other defect in the diet. At any rate, I have never been able to restore the appetite by increasing the amount of vitamin B in the diet.

The principal sources of B-1 are whole grains, wheat germ, yeast, the glandular organs, and the yolk of egg. Other sources are tomatoes, raw cabbage, fresh spinach and the legumes. Milk contains relatively little.

Vitamin G (B2) A marked deficiency of G causes pellagra. A moderate deficiency results in various forms of dermatitis and is said to cause loss of appetite and impairment of growth. What has been said as to loss of appetite and impairment of growth in relation to B-1 applies also to G.

The sources of vitamin G in order of efficiency are liver, yeast, meat, milk solids, egg yolk, and whole grains.

Vitamin C—the antiscorbutic vitamin. A marked deficiency of this vitamin is, as is well known, the cause of scurvy. Symptoms of a moderate deficiency are defective development of the teeth, with dental caries, diminished resistance to infection, changes in the blood vessels and a tendency to hemorrhage, loss of appetite and anemia. It must be remembered in attributing defective development of the teeth and dental caries to an insufficiency of this vitamin that the teeth of guinea pigs grow continuously while those of man do not. Conclusions based on experiments on animals may not be therefore, justified for man. It is very difficult to prove, moreover, that a deficiency of vitamin C really diminishes resistance to infection in man.

It is hardly necessary to discuss the sources of vitamin C. Every baby gets either orange juice or tomato juice nowadays, whether it needs it or not. Scurvy is, however, a medical curiosity in the breast-fed. It was very uncommon in babies fed on raw cows' milk, although of course, it is well known that the amount of the antiscorbutic vitamin in milk varies with the time of year and the food of the cows. Now, when all babies are fed on pasteurized, boiled or dried milk, an antiscorbutic is a necessity.

Vitamin D—the antirachitic vitamin. So much has been written about this vitamin, rickets, fish oils, viosterol, irradiated foods and ultraviolet irradiation during the last few years that I, for one, am tired of it all. The medical journals are all cluttered up with advertisements of antirachitics and my mail is full of samples. Fortunately, I can usually keep the detail men out. There is no doubt, of course, that an insufficiency of vitamin D or of its activator, the ultraviolet rays, will result in the development of rickets. It undoubtedly also has something to do with the development of spasmodic hiccups and with defective development and caries of the teeth. There is also no doubt that vitamin D will cure these conditions. It must be remembered, however, that in all these conditions a proper supply of available Ca and P is as necessary as the vitamin. It is also true that a slight amount of rickets is not a serious condition. Too much stress is being laid upon it. Furthermore, as Eliot and her co-workers have recently shown, the clinical diagnosis of mild rickets is often wrong.

There are many sources of this vitamin. Fish oils contain the most. Animal fats contain some, vegetable fats little or none. The amount in egg yolks varies. The grains contain none. Oatmeal is said to do harm. Cows' milk contains little. It, like other foods can be irradiated. Vitamin D can also be introduced into milk by feeding irradiated yeast to the cows. The ergosterol in the skin can be activated by exposing the body to the sun's rays or to those from various lamps.

Fortunately there is practically no danger of getting an excess of vitamin D clinically, although experimentally serious results have been produced by an excess. It is lucky that this is so, because, if it were not, a good many babies that are taking various fish oils, viosterol, irradiated foods, and going about naked would be in serious difficulties.

In this part of the world it is probably advisable to see that babies get vitamin D in some form during all but the summer months. In fact, there is no doubt that, by and large, in spite of all that I have just said, babies have been much benefited by the general use of vitamin D during the last few years. There seems to be no valid reason, however for giving it to children as a routine procedure.

To sum up. Practically, if a child gets a reasonable amount of milk, an occasional egg, some meat, and whole grains, it is very unlikely to lack vitamins. If the milk is not raw, a baby needs an antiscorbutic. It is a good thing for a child to have some vegetables as an additional safeguard. Spinach and other "leafy" vegetables are not, however, as necessary as many would lead us to believe. It is advisable to give babies vitamin D in some form during the winter months.

SALTS. It is impossible to discuss the salts in detail in a paper of this sort. The subject is altogether too complicated and has too many ramifications. The food must contain certain salts in sufficient amounts. Furthermore, these salts must be present in such a form that they can be absorbed and utilized. There may be plenty of them and yet they may be practically useless because of the form which they are in or because of the presence of or lack of other factors. For example, the absorption of Ca and P depends on the relative proportions of each and the reaction of the intestinal contents, the utilization of Ca depends on the amount of vitamin D and the activity of the parathyroids, and so on. Furthermore, the availability of the salts also depends on the various amounts of the various food elements—fats, carbohydrates and proteins—in the diet. In general, an excess of one of the salts is unimportant, unless it interferes with the absorption or utilization of some other salt. The excess is simply not absorbed or it is promptly eliminated. A deficiency of one or more of the salts is the important thing.

The salts which are of practical importance are those of Ca, P, Fe, and I. We can safely forget copper, cobalt and manganese! It is very difficult to state just what the needs for these elements are because of the complicating factors just mentioned. Roughly, a child needs one gram of Ca and one and half grams of P per day. It is hard to see how a child that is taking milk, eggs and cereal can fail to get enough.

A retention of one half a milligram of iron a day is required during the first six months of one milligram during the rest of the first year, and of two milligrams during the rest of childhood. In general it is still safe to assume that the store of iron in the liver of the average infant is sufficient to make up for the deficiency of iron in the milk during the first six months. Milk is of course, notoriously low in iron. Eggs, prunes and green vegetables are the best source. The relative importance of the latter has, however, been much exaggerated. This has been shown by Schlutz and his co-workers in a recent paper.

The need for iodine is one tenth of a milligram per day. In this part of the country it does not need to be considered. This is especially true when we remember that almost every baby and child in this vicinity is taking syrup of hydriodic acid.

WATER. It is hardly necessary to take up the water needs in detail. It must be a very unusual occurrence for either a baby or a child not to get enough water to cover its metabolic

needs. In many instances, however, it would be better for it to get more.

SUMMARY. I have endeavored to show what a child needs and must have in its diet in order to be well and to grow satisfactorily. It is evident, it seems to me, that the individual child needs just so much of the various food elements, salts and vitamins, no more, no less. If he takes more, it is wasted, if he takes less, he must suffer for the lack of it. The minimum diet is, therefore, the one diet which meets the child's needs that is the ideal or optimal diet. If he gets less than this, he will not starve to death and may not show any striking evidences of disease, but he cannot thrive and develop as he should. This minimum diet should be the aim and guide of those who are prescribing the diets for the poor and undernourished children. This diet may vary very much in cost according to the amount of knowledge and skill which are used in its selection and preparation. It need not be, and ought not to be, expensive. In fact, it may and should cost very much less than many diets which do not meet the nutritive needs nearly so well.

THE USE OF ERGOTAMINE TARTRATE IN MIGRAINE*

BY WILLIAM G. LENNOX, M.D.†

DRUGS used for the relief of migraine are in most part sedatives, burying the pain but not righting the condition responsible for the pain. Moreover, with many patients the headache seizures are so severe that even strong sedatives do not give relief. Any non-sedative drug which in the majority of patients will cut short a severe migraine attack deserves thorough clinical trial and careful experimental study.

Ergotamine tartrate (which is sold under the trade name of "Gynergen") was called to my attention by Dr. Stephen J. Maddock, who had used it with dramatic results in a patient with migraine whose attacks had not been relieved by any of many treatments tried. A search of the literature disclosed several communications on the subject from European authors. Maier¹ in 1926, in an article dealing with the effects of ergotamine tartrate on the sympathetic nervous system, says that he has used it successfully in cases of pruritus migraine and epilepsy. Cornil² recites a case whose migraine headaches could be stopped by the oral administration of the drug. There are also case reports in theses which cannot be consulted, viz., Déclaire³ of

Bordeaux in 1926 and Cantils of Montpellier in 1929.

The first and also the largest series of cases has been that of Tzanck^{4, 5}. In 1928 he reported 12 cases and in 1931 101. In his first report he states that of eight cases of typical and chronic migraine resistant to all previous treatment, all had been favorably influenced. Of three other patients with almost continuous headache, two had been almost completely cured and one had discontinued treatment because of painful menstruation. One other patient with ophthalmic migraine had been relieved of headaches but not of the ocular symptoms. Tzanck's analysis of results in his last reported series of 101 cases is disappointingly brief and indefinite. He states that 15 out of the 44 members of the group which he calls "typical" had been "cured" and the condition of nearly all ameliorated, and that results were even more favorable in patients having a migraine state. By this term he means attacks which are less clear cut and violent. Some patients were apparently "cured", some had attacks at longer intervals, some developed a tolerance for the drug requiring larger and larger doses for relief. Tzanck gave the ergotamine by mouth, from one to as high as six mg. a day, or subcutaneously 0.5 mg. twice a day. Besides treating individual attacks he speaks of the prophylactic use of daily doses. Trautmann⁶, at about the same time as Tzanck

From the Department of Neuropathology of the Harvard Medical School and the Neurological Unit of the Boston City Hospital. The investigation was aided by a grant from the Josiah Macy Jr. Foundation.

Vitamin C—the antiscorbutic vitamin A marked deficiency of this vitamin is, as is well known, the cause of scurvy. Symptoms of a moderate deficiency are defective development of the teeth, with dental caries, diminished resistance to infection, changes in the blood vessels and a tendency to hemorrhage, loss of appetite and anemia. It must be remembered in attributing defective development of the teeth and dental caries to an insufficiency of this vitamin that the teeth of guinea pigs grow continuously while those of man do not. Conclusions based on experiments on animals may not be therefore, justified for man. It is very difficult to prove, moreover, that a deficiency of vitamin C really diminishes resistance to infection in man.

It is hardly necessary to discuss the sources of vitamin C. Every baby gets either orange juice or tomato juice nowadays, whether it needs it or not. Scurvy is, however, a medical curiosity in the breast-fed. It was very uncommon in babies fed on raw cows' milk, although of course, it is well known that the amount of the antiscorbutic vitamin in milk varies with the time of year and the food of the cows. Now, when all babies are fed on pasteurized, boiled or dried milk, an antiscorbutic is a necessity.

Vitamin D—the antirachitic vitamin. So much has been written about this vitamin, rickets, fish oils, viosterol, irradiated foods and ultraviolet irradiation during the last few years that I, for one, am tired of it all. The medical journals are all cluttered up with advertisements of antirachitics and my mail is full of samples. Fortunately, I can usually keep the detail men out. There is no doubt, of course, that an insufficiency of vitamin D or of its activator, the ultraviolet rays, will result in the development of rickets. It undoubtedly also has something to do with the development of spasmophilia and with defective development and caries of the teeth. There is also no doubt that vitamin D will cure these conditions. It must be remembered, however, that in all these conditions a proper supply of available Ca and P is as necessary as the vitamin. It is also true that a slight amount of rickets is not a serious condition. Too much stress is being laid upon it. Furthermore, as Eliot and her co-workers have recently shown, the clinical diagnosis of mild rickets is often wrong.

There are many sources of this vitamin. Fish oils contain the most. Animal fats contain some, vegetable fats little or none. The amount in egg yolks varies. The grains contain none. Oatmeal is said to do harm. Cows' milk contains little. It, like other foods can be irradiated. Vitamin D can also be introduced into milk by feeding irradiated yeast to the cows. The ergosterol in the skin can be activated by exposing the body to the sun's rays or to those from various lamps.

Fortunately there is practically no danger of getting an excess of vitamin D clinically, although experimentally serious results have been produced by an excess. It is lucky that this is so, because, if it were not, a good many babies that are taking various fish oils, viosterol, irradiated foods, and going about naked would be in serious difficulties.

In this part of the world it is probably advisable to see that babies get vitamin D in some form during all but the summer months. In fact, there is no doubt that, by and large, in spite of all that I have just said, babies have been much benefited by the general use of vitamin D during the last few years. There seems to be no valid reason, however, for giving it to children as a routine procedure.

To sum up. Practically, if a child gets a reasonable amount of milk, an occasional egg, some meat, and whole grains, it is very unlikely to lack vitamins. If the milk is not raw, a baby needs an antiscorbutic. It is a good thing for a child to have some vegetables as an additional safeguard. Spinach and other "leafy" vegetables are not, however, as necessary as many would lead us to believe. It is advisable to give babies vitamin D in some form during the winter months.

SALTS It is impossible to discuss the salts in detail in a paper of this sort. The subject is altogether too complicated and has too many ramifications. The food must contain certain salts in sufficient amounts. Furthermore, these salts must be present in such a form that they can be absorbed and utilized. There may be plenty of them and yet they may be practically useless because of the form which they are in or because of the presence of or lack of other factors. For example, the absorption of Ca and P depends on the relative proportions of each and the reaction of the intestinal contents, the utilization of Ca depends on the amount of vitamin D and the activity of the parathyroids, and so on. Furthermore, the availability of the salts also depends on the various amounts of the various food elements—fats, carbohydrates and proteins—in the diet. In general an excess of one of the salts is unimportant, unless it interferes with the absorption or utilization of some other salt. The excess is simply not absorbed or it is promptly eliminated. A deficiency of one or more of the salts is the important thing.

The salts which are of practical importance are those of Ca, P, Fe, and I. We can safely forget copper, cobalt and manganese! It is very difficult to state just what the needs for these elements are because of the complicating factors just mentioned. Roughly, a child needs one gram of Ca and one and half grams of P per day. It is hard to see how a child that is taking milk, eggs and cereal can fail to get enough.

go to my Saturday morning class and to carry on my usual activities during the day which is the first time within the experience of these headaches that I have been able to do so

In the majority of cases, nausea or vomiting, or both, occurred before the headache began to lessen. Vomiting was not, however, a necessary preliminary to relief. In these patients relief began after the administration of the drug in the following period of time, viz, intravenously, 15-30 minutes, subcutaneously, one to two hours, orally, two to three hours. The order of effectiveness was the same, intravenous or intramuscular most, subcutaneous next, and oral, a poor third. Although dosage by mouth was double that used by needle, patients whose headaches were severe, were not ordinarily helped by oral administration. A few found that tablets taken by mouth would stop the milder headaches or make severe ones more bearable.

Ergotamine tartrate is marketed in ampules containing either 0.25 mg or 0.5 mg of the drug, and in tablets containing 1.0 mg. The recommended single dose is 0.5 mg subcutaneously or 1.0 mg by mouth. Because patients vary in their reaction to the drug it is probably wise to give but half the full subcutaneous dose at the first trial. If this is well borne but not effective, the full dose can then be given. The dosage can be repeated after an interval of two to three hours. For a prompt sustained effect, I prefer to give 0.5 cc (0.25 mg) intravenously and, at the same time the same amount subcutaneously. The dose should be varied in order to find the least amount which is effective. It is presumably more effective if given early in the attack.

Besides the nausea and vomiting experienced by many of the patients, three complained of dyspnea and a sense of constriction in the chest. One of these patients, Mrs. T., who received 0.5 mg intravenously, had, along with this, symptoms of angina, and an increase in blood pressure from a preinjection level of 142 systolic and 90 diastolic, to a height of 180 systolic and 160 diastolic. Although Meakins and Scriver¹⁵ gave as high as 18 mg by mouth daily for 20 days to patients with hypertension, it would seem wise to use ergotamine cautiously in patients with vascular disease. Following injection, there is usually increase in systolic and decrease in pulse pressure and bradycardia. After the headache ceased, a feeling of fatigue or muscle soreness was common. One patient believed that menstruation was made more profuse. Pregnancy is, of course, a contraindication.

What has been said applies to the treatment of headaches after they have begun. Can ergotamine be used to prevent the seizure? Unfortunately the danger of ergotism makes the daily administration of ergotamine over a prolonged period questionable and most patients do not have attacks with such regularity that treat-

ment can be concentrated in a preheadache period. Several of the patients had headaches in spite of taking 3 mg by mouth daily. One of these, by taking 9 mg daily, apparently skipped two headaches, but finally had one in spite of this large dosage. I doubt the feasibility of preventing attacks by this medicine.

Although the immediate results in most patients are gratifying, the question of the value of continued use of ergotamine is important. Some of the European authors speak hopefully of a lessening or disappearance of attacks. One of our patients who was having headaches at about weekly intervals, since receiving three injections has not had an attack in two months. We doubt, however, if in our average case the interval between attacks has been altered.

Certain of our observations temper enthusiasm concerning long range prospects. Patients whose attacks are terminated when treatment is first instituted may later on fail, at times, to obtain relief, or else the interval between attacks may be shortened. There is some evidence that in epilepsy the use of antispasmodic drugs may act only as a dam, postponing but not, in the long run, preventing attacks. The same may be true in certain severe cases of migraine. At any rate, evaluation of the clinical worth of the drug must await a longer experience.

The experience of the eight patients whose headaches were frequent and incapacitating who had had no relief from the usual drugs and who began to use ergotamine more than six months ago will be given briefly. The first six patients are women.

A housewife aged 54 has had frequent incapacitating hemicrania with nausea and vomiting since childhood. Besides various medical treatments she had submitted to removal of her gall bladder and of her cervical sympathetic nerves without even temporary relief. Headaches which lasted two to three days recurred every week or ten days. In addition in recent years she has had almost daily moderate headaches for which she uses headache powders. Ergotamine tartrate has been used subcutaneously for 18 months. Each time it stops the headache but on some occasions the pain has returned and there has been a tendency for attacks to recur more frequently. She now takes 0.5 mg subcutaneously almost daily. Her suffering is greatly reduced but she is still in the coils of this disease.

A high school Latin instructor aged 36 with a history of migraine since childhood has an attack about once a week which lasts for two days. Vomiting which is profuse was formerly followed by relief of headache but is not now. She has very poor posture and musculature, visceroptosis and constipation. Each of the several dozen attacks which have assailed her in the last nine months has disappeared about 75 minutes after subcutaneous injection of 0.3 mg of ergotamine tartrate. Vomiting is violent. After the headache subsides she is weak and does not regain her strength before the next attack occurs. The interval between headaches has not changed. The individual attacks have been robbed of their terror but her general situa-

reported the use of ergotamine tartrate in 30 cases of migraine. The results are not tabulated. The author merely states that, except in individual instances, one or two mg of the drug by mouth would begin to relieve the headache in about one-half hour, and that it was without effect in headaches associated with organic brain injury. An indifferent agent was given first in order to rule out the factor of suggestion. Targhetta⁷ reported successful termination of attacks in one case. Ignelzi⁸ had favorable results in six cases. He gave the drug intramuscularly in 0.5 mg doses. Kottmann⁹ reported treatment in five patients. Subcutaneous medication relieved each attack. Little success attended oral or rectal administration. One patient, however, who had monthly headaches at the time of menstruation, took six mg of ergotamine by mouth daily for five days before headache was expected, and for four months had no attack. Riley¹⁰, in his monograph on migraine, states that Tilney recommends ergotamine tartrate, either alone or combined with bellafoline.

Mignot¹¹ has no cases to report but reviews the literature, naming the various medical conditions in which ergotamine has been used, and discussing the dosage.

These authors do not mention serious untoward results from the use of ergotamine tartrate. The drug has been used extensively by obstetricians and gynecologists to control uterine hemorrhage, and by internists in the treatment of exophthalmic goiter, glaucoma, hypertension, auricular tachycardia, and pruritus of hepatic or of renal origin. Zorn¹² detailed four cases (one his own and three from the literature) in which use of ergotamine tartrate was followed by symptoms suggestive of beginning gangrene of the extremities. Oginski¹³ reported a case of puerperal sepsis in which six drams of fluid extract of ergot and 22 mg of ergotamine were given in a period of fourteen days. The patient developed gangrene of the feet. Three patients with exophthalmic goiter in which cerebral vascular accidents occurred in the course of treatment were reported by Labbé¹⁴ and his associates. In these various reports, it is not clear that the injections were mainly responsible. In addition to these grave sequelae, authors speak of nausea and vomiting and sometimes of precordial pain which follows administration of the drug.

Because of the favorable reports in the literature as well as the surprising results in my own preliminary trial of the drug, I have, in the past eighteen months used ergotamine tartrate for all migraine patients who have been willing to experiment with it*. The experience is too short and the cases too few to make de-

tailed analysis profitable. I shall give such general results and experiences as will aid those who wish to make trial of the drug.

To date, ergotamine tartrate has been given to 45 patients (6 men and 39 women) while they were suffering from a headache of the migraine type. Abrupt termination of the headache in question occurred in 40 of the 45 patients. Of the remaining patients, three had no relief whatsoever, two patients had no immediate relief but the attack was apparently shortened by two days.

In migraine, emotional factors often play a prominent part. Hence, an attitude of skepticism on the part of the clinician toward apparent immediate results is essential. Perhaps "suggestion" and not medicine stopped the pain. In order to minimize suggestion, patients were warned that they were to be given the ergotamine (which sometimes helped headaches) as an experiment. Most of them considered this just another straw to be grasped at. The uniformity of the time interval between injection and relief, the fact that this interval was different for intravenous and subcutaneous injections (which difference patients did not expect), the fact that in the past other drugs and procedures had not been even temporarily effective for most of these patients, and, finally the absence of relief from the injection of water (tried in a few patients), argued against suggestion as the explanation for the relief.

Of course, a certain small proportion of patients will obtain relief in the first trial of any new medicine or procedure. For nearly 90 per cent of migraine patients to obtain abrupt release from pain with the initial use of a drug is outside my experience. To some of the patients, the dramatically abrupt and complete termination of the headache, the sudden release from a state of misery, seemed almost miraculous. In the experience of these patients an attack once aborted rarely returned. Unlike hypnotics, the relief persisted beyond the period of action of the drug. After the pain had disappeared, there was usually a feeling of lassitude. The following description of events from a patient's report is fairly typical.

"The headache began to make its appearance about four o'clock in the afternoon and gradually increased in severity until about seven o'clock when I was quite sure I was in for a regular one and so decided to make use of 'Gynergen'. I had it injected (0.5 mg subcutaneously) into my right arm and went to bed. A half an hour previous to this I had consumed a generous dinner as I was as usual very hungry. After being in bed for about fifteen minutes I began to feel very nauseated and at regular intervals for about twenty minutes I vomited continuously. Being somewhat exhausted I fell asleep and slept until about 3 A.M. On waking to my great surprise and relief the headache had completely vanished. I felt extremely tired, as if I had had a very active day out-of-doors but it was a pleasant feeling of fatigue and I turned over and slept until about 7:30 A.M. I was able to

*The ergotamine tartrate (Gynergen) used in these trials was supplied by the Sandoz Chemical Works of New York City. Seven of the patients were treated by a colleague, Dr. T. J. C. von Storch. Dr. Stephen Maddock, Dr. H. S. Forbes, or Dr. Philip Solomon.

go to my Saturday morning class and to carry on my usual activities during the day which is the first time within the experience of these headaches that I have been able to do so

In the majority of cases, nausea or vomiting, or both, occurred before the headache began to lessen. Vomiting was not, however, a necessary preliminary to relief. In these patients relief began after the administration of the drug in the following period of time, viz, intravenously, 15-30 minutes, subcutaneously one to two hours, orally, two to three hours. The order of effectiveness was the same: intravenous or intramuscular, most, subcutaneous next and oral, a poor third. Although dosage by mouth was double that used by needle, patients whose headaches were severe, were not ordinarily helped by oral administration. A few found that tablets taken by mouth would stop the milder headaches or make severe ones more bearable.

Ergotamine tartrate is marketed in ampules containing either 0.25 mg or 0.5 mg of the drug, and in tablets containing 1.0 mg. The recommended single dose is 0.5 mg subcutaneously or 1.0 mg by mouth. Because patients vary in their reaction to the drug, it is probably wise to give but half the full subcutaneous dose at the first trial. If this is well borne but not effective, the full dose can then be given. The dosage can be repeated after an interval of two to three hours. For a prompt sustained effect, I prefer to give 0.5 cc (0.25 mg) intravenously and, at the same time, the same amount subcutaneously. The dose should be varied in order to find the least amount which is effective. It is presumably more effective if given early in the attack.

Besides the nausea and vomiting experienced by many of the patients, three complained of dyspnea and a sense of constriction in the chest. One of these patients, Mrs. T., who received 0.5 mg intravenously, had, along with this, symptoms of angina, and an increase in blood pressure from a preinjection level of 142 systolic and 90 diastolic, to a height of 180 systolic and 160 diastolic. Although Meakins and Scriver¹⁵ gave as high as 18 mg by mouth daily for 20 days to patients with hypertension it would seem wise to use ergotamine cautiously in patients with vascular disease. Following injection, there is usually increase in systolic and decrease in pulse pressure and bradycardia. After the headache ceased, a feeling of fatigue or muscle soreness was common. One patient believed that menstruation was made more profuse. Pregnancy is, of course, a contraindication.

What has been said applies to the treatment of headaches after they have begun. Can ergotamine be used to prevent the seizure? Unfortunately, the danger of ergotism makes the daily administration of ergotamine over a prolonged period questionable and most patients do not have attacks with such regularity that treat-

ment can be concentrated in a preheadache period. Several of the patients had headaches in spite of taking 3 mg by mouth daily. One of these, by taking 9 mg daily, apparently skipped two headaches, but finally had one in spite of this large dosage. I doubt the feasibility of preventing attacks by this medicine.

Although the immediate results in most patients are gratifying, the question of the value of continued use of ergotamine is important. Some of the European authors speak hopefully of a lessening or disappearance of attacks. One of our patients who was having headaches at about weekly intervals, since receiving three injections has not had an attack in two months. We doubt, however, if in our average case the interval between attacks has been altered.

Certain of our observations temper enthusiasm concerning long range prospects. Patients whose attacks are terminated when treatment is first instituted may later on fail at times, to obtain relief, or else the interval between attacks may be shortened. There is some evidence that in epilepsy the use of antispasmodic drugs may act only as a dam, postponing but not, in the long run, preventing attacks. The same may be true in certain severe cases of migraine. At any rate, evaluation of the clinical worth of the drug must await a longer experience.

The experience of the eight patients whose headaches were frequent (and incapacitating, who had had no relief from the usual drugs and who began to use ergotamine more than six months ago will be given briefly. The first six patients are women.

A housewife aged 54 has had frequent incapacitating hemiparesis with nausea and vomiting since childhood. Besides various medical treatments she had submitted to removal of her gall bladder and of her cervical sympathetic nerves without even temporary relief. Headaches which lasted two to three days recurred every week or ten days. In addition in recent years she has had almost daily moderate headaches for which she uses headache powders. Ergotamine tartrate has been used subcutaneously for 18 months. Each time it stops the headache but on some occasions the pain has returned and there has been a tendency for attacks to recur more frequently. She now takes 0.5 mg subcutaneously almost daily. Her suffering is greatly reduced but she is still in the coils of this disease.

A high school Latin instructor aged 36 with a history of migraine since childhood has an attack about once a week which lasts for two days. Vomiting which is profuse was formerly followed by relief of headache but is not now. She has very poor posture and musculature, visceroptosis and constipation. Each of the several dozen attacks which have assailed her in the last nine months has disappeared about 75 minutes after subcutaneous injection of 0.3 mg of ergotamine tartrate. Vomiting is violent. After the headache subsides she is weak and does not regain her strength before the next attack occurs. The interval between headaches has not changed. The individual attacks have been robbed of their terror but her general situa-

tion is, at present, no better than when treatment was started.

A postgraduate college student of 32 years has had incapacitating headaches lasting two to five days since adolescence, the frequency in recent years being once or twice a month. Each of the attacks treated in the last year was aborted, although she has not taken an injection for every headache because of the unpleasant gastric symptoms. In recent months, the interval between attacks has been greatly increased, possibly as a result of dietary treatment.

A bank official, aged 44, has had headaches at about monthly intervals for 11 years. With each attack she has been away from her office under morphine medication for from two to six days. In the past 15 months, each of her attacks has been terminated by an injection of ergotamine, so that each time she has lost no more than a day from work. Headaches are somewhat more frequent than in the pretreatment period.

A housewife, aged 41, who conducts a beauty parlor, has had severe headaches since her marriage, 21 years ago. They come about three times a month, each lasting 24-48 hours. There are also other mild headaches, not migrainous in type, which come frequently but irregularly. She has had mild hypertension for years, and six years ago had an infarct of a kidney. She is the patient already mentioned, who has anginal symptoms after intravenous or subcutaneous injections. She has been under observation for a year. Although each injection gives abrupt relief, her cardiovascular symptoms have forced resort to oral administration. This method is not nearly so effective but 2 mg shortens the period of incapacity. The patient's "ordinary" headaches are not helped by ergotamine. In the last six months, probably as a result of a vacation, she has had but few attacks.

A housewife and physician has had incapacitating headaches lasting two to three days since girlhood. A headache always accompanies menstruation and may appear in an interval also. She has taken ergotamine for nearly two years—except during the nine months of pregnancy when she was free of headaches. Each headache has been aborted. The interval between headaches is reduced to ten days or two weeks.

A male physician of 47 years for the last three years has had attacks of right hemiparesis, coming two to five times a week, each attack lasting two to six hours. The diagnosis in this case (the only one of the series) is questionable. He does not have nausea or vomiting. There is localized tenderness of the scalp and the pain radiates into the right arm. Attacks were uniformly aborted for three months by ergotamine tartrate taken either by mouth (the method preferred by the patient) or by injection. In the last three months, however, repeated trial has been without avail.

A male factory worker, aged 28, has had ophthalmic migraine (with an aura of homonymous hemianopsia) about once a month for nine years. The aura has on seven occasions ushered in a convulsion in place of a headache. The stellate ganglion of one side was removed by Dr. Donald Munro 18 months ago and the patient was free of headaches for several months. Ergotamine has been taken for many of the attacks in the last year with abortion of each attack. He has not had a severe headache with visual aura for four months. Milder attacks are controlled by ergotamine taken orally.

On the basis of this preliminary experience it seems probable that patients with frequently recurring and very severe headaches may not

find permanent help in ergotamine tartrate. Those mildly affected, who obtain relief from one of the sedatives, will not care to change. But many persons in a middle group, who have attacks of moderate severity and who do not get relief from the usual remedies, may find ergotamine tartrate a godsend. The distracted physician to migraine patients has a new weapon in his armamentarium. These remarks refer only to the medicine as a palliative, giving symptomatic relief for individual attacks. The prevention of attacks, the "cure" of migraine is a different matter. The successful use of a drug should never displace efforts to correct underlying physical or emotional abnormalities.

DISCUSSION

What is the mechanism by which, on occasion, ergotamine tartrate so decisively puts the pain of migraine to flight? Among other actions, the drug stimulates the contraction of smooth muscle and depresses the activity of the sympathetic nervous system. In the latter respect, it is the antagonist of adrenalin. The authors who have been quoted accept the theory of vascular spasm as the cause of migraine and assume that ergotamine paralyzes the motor sympathetics and thereby relieves the spasm and the pain. On the other hand, one might assume that small doses of ergotamine act on sensory nerves with elimination of painful stimuli but without necessarily altering the calibre of vessels and the cerebral blood flow. In this connection, the relief of pruritus by ergotamine tartrate is suggestive. The time interval between injection and relief is the same for both pruritus and headache. As yet unexplained is the fact that after subcutaneous injection, blood pressure changes and uterine contractions begin almost at once but relief of headache does not begin for nearly an hour.

In the case of one of our patients, we have therapeutic evidence against the exclusive importance of the sympathetic nervous system. She is the patient already mentioned, who had complete bilateral sympathectomy by an excellent neurosurgeon in Baltimore. The operation did not influence headaches, but ergotamine aborted each attack. With the sympathetic pathways obliterated, how did the ergotamine act?

Does ergotamine help only patients with migraine? This question of specificity is important for etiological studies. Trautmann⁶ and Kottmann⁷ state that ergotamine does not influence non-migrainous headaches. Indeed, the latter contends that if ergotamine is not effective the patient is vagotonic. In our experience, however, ergotamine may terminate headaches which cannot be classed as migraine.

Certainly, the theory of the mechanism by which the drug works requires experimental testing. We are interested in ergotamine tartrate principally because of our hope that study will

disclose the physiological mechanism by which it affords such abrupt relief. If we can learn why it stops a headache perhaps we may learn why the headache started, and thus have a basis for more rational treatment. A group of us are conducting a clinic for patients with migraine at the Boston City Hospital and carrying out a coöperative attack on the problem. The physiological effect of ergotamine tartrate on patients, especially as regards cerebral circulation, will be the subject of future communications.

CONCLUSIONS

Ergotamine tartrate has been given by intravenous or subcutaneous injection to 45 migraine patients while they were having a headache.

Abrupt termination of the initial attack treated occurred in 40 of the 45 patients. Eight of the patients had had frequent incapacitating headaches for many years had not found relief by other drugs or treatment and have used ergotamine tartrate for six months or longer. Seven of these have had almost uniform relief for individual attacks. Of these seven four are having attacks at more frequent and three at less frequent intervals than before medication was started.

Study of the mechanism by which ergotamine tartrate so often gives such dramatic relief is in progress.

THE PARENTERAL ADMINISTRATION OF PARALDEHYDE FOR THE CONTROL OF PAIN AND CONVULSIVE STATES

BY ALLEN S. JOHNSON, M.D.*

PARALDEHYDE was introduced by Cervello in 1882 but its use as a hypnotic has been greatly hampered by reason of its disagreeable odor and taste which may be constantly apparent to the patient for twenty-four hours after administration. Rectal administration has only partly overcome this difficulty as the rapid and persistent elimination by the lungs gives rise to considerable discomfort. Because of these drawbacks the drug might have fallen into disuse were it not for the rapidity of its action and the large margin of safety between the hypnotic and the fatal dose. Five to 10 cc diluted with water or some other vehicle represents the usual hypnotic dose by mouth or rectum. The lethal dose on the other hand is probably not less than 50 cc though reports of fatal paraldehyde poisoning are difficult to find. Bastedo¹ states that death has occurred from 60 cc given by rectum but also reports a case that recovered after the administration of 100 cc. Sollmann² says "Its acute toxicity is low so that one hundred grams produced only very prolonged sleep." I have safely given 60 cc intramuscularly in the course of twenty-

four hours to relieve the pain of carcinoma of the bladder which could no longer be controlled by morphine. The safety of paraldehyde obviously lies in the fact that it is rapidly eliminated and does not depress the circulatory and respiratory systems until very high concentrations have been reached. But the unpleasant characteristics of the drug have limited its use in the treatment of pain and to the control of delirium tremens where effectiveness and safety of action are more important than the aesthetic objections of the patient.

In 1912 Noel and Souttar³ reported the intravenous use of equal parts of paraldehyde and ether in normal saline. "Deep anesthesia" may be very rapidly produced,—hypnotic effect excellent. It is well to give with an amount of ether. The action of the drug is rapid hence best given diluted. 5-15 cc of paraldehyde is mixed with an equal quantity of ether. This mixture is dissolved in 150 cc cold solution of sodium chloride (1%) in water. Inject the solution cold or at not exceeding 25°C. Fildes and McIntosh⁴ Injection apparatus is used. Five seconds after injection the patient tastes paraldehyde in forty seconds.

DISCUSSION

What is the mechanism by which, on occasion, ergotamine tartrate so decisively puts the pain of migraine to flight? Among other actions, the drug stimulates the contraction of smooth muscle and depresses the activity of the sympathetic nervous system. In the latter respect, it is the antagonist of adrenalin. The authors who have been quoted accept the theory of vascular spasm as the cause of migraine and assume that ergotamine paralyzes the motor sympathetics and thereby relieves the spasm and the pain. On the other hand, one might assume that small doses of ergotamine act on sensory nerves with elimination of painful stimuli but without necessarily altering the calibre of vessels and the cerebral blood flow. In this connection, the relief of pruritus by ergotamine tartrate is suggestive. The time interval between injection and relief is the same for both pruritus and headache. As yet unexplained is the fact that after subcutaneous injection, blood pressure changes and uterine contractions begin almost at once but relief of headache does not begin for nearly an hour.

In the case of one of our patients, we have therapeutic evidence against the exclusive importance of the sympathetic nervous system. She is the patient already mentioned, who had complete bilateral sympathectomy by an excellent neurosurgeon in Baltimore. The operation did not influence headaches, but ergotamine aborted each attack. With the sympathetic pathways obliterated, how did the ergotamine act?

Does ergotamine help only patients with migraine? This question of specificity is important for etiological studies. Trautmann⁶ and Kottmann⁷ state that ergotamine does not influence non-migrainous headaches. Indeed, the latter contends that if ergotamine is not effective the patient is vagotonic. In our experience, however, ergotamine may terminate headaches which cannot be classed as migraine.

Certainly the theory of the mechanism by which the drug works requires experimental testing. We are interested in ergotamine tartrate principally because of our hope that study will

could be adequately controlled with morphine

Intravenous paraldehyde in 7 to 10 cc doses has also been used to control the restlessness and headache of a hypertensive patient with evidence of extensive cerebro-vascular pathology. This patient⁶ was violently nauseated by morphine and was unable to retain the barbituric acid derivatives by mouth or rectum. Quiet sleep was induced on each of six successive nights by the intravenous administration of 7 cc of paraldehyde. The sleep so induced would last several hours but could be greatly prolonged by the rectal injection of sodium amytal Gr V-X which was retained if given after consciousness had been lost. It is interesting to note that this patient began to show some degree of tolerance to paraldehyde after two or three injections, as there developed a latent period of ten to fifteen minutes between the injection and the onset of deep sleep. Such cases are probably not proper subjects for this treatment as then pain is hardly severe enough to warrant anesthesia and the relief from minor symptoms is too transient to be of much help in the long run. In this particular case intravenous paraldehyde was used because we had apparently exhausted every other method of giving the patient quiet sleep. When this type of patient reaches the convulsive stage, however, parenteral paraldehyde is the treatment of choice as its action is swift and an anesthetic dose is

well within the limits of safety. Here it is often superior to morphine, for many of these patients have developed a degree of tolerance which makes difficult the estimation of a dose which will be immediately effective yet safe.

Tolerance to paraldehyde unquestionably develops and habit formation has been reported, but these should not be problems if the drug is used only occasionally to control severe pain or convulsive states requiring rapid anesthesia.

It must be admitted that paraldehyde, however administered, is unpleasant and for that reason it is not the first choice for the relief of pain. But it is cheap, stable, easy to procure, requires no sterilizing and has a wide margin of safety while being almost instantaneous in action when administered parenterally. This makes it an exceedingly useful drug for the control of convulsive states and for the relief of pain which is unaffected by morphine.

FOREIGN PROTEIN SENSITIZATION WITH MENINGEAL INVOLVEMENT DUE TO THE USE OF VACCINE*

BY WILLIAM E. HALL, M.D.,† AND THOMAS P. MURDOCK, M.D.‡

FOREIGN protein sensitization with involvement of the meninges has not been dealt with extensively in American literature. The clinical picture is alarming. We feel that the disease occurs more frequently than has been believed and because of this the importance of the condition should be stressed.

Swift and Boots¹ go so far as to say that most patients receiving considerable amounts of therapeutic serum develop serum disease. If this is so and certainly there seems to be sufficient evidence to support it the condition warrants more than passing notice. The present tendency toward subcutaneous intramuscular, and intravenous injections of foreign proteins will in all probability increase the frequency of protein sensitivity, and also the more serious meningeal complications. Serum disease seems much more likely to follow the use of scarlet fever antistreptococcus serum than any of the other serums.

In 1926 Kennedy² reported severe symptoms referable to the central nervous system in three patients with angioneurotic edema which he attributed to a focal edema of the brain. In 1928³ he also reported several cases of involvement of the nervous system, and one case showing meningeal signs and symptoms following administration of serum. He suggested two possibilities as causative factors. The toxicity of the serum, or the urticarial edema of the perineural tissue.

Sheppe⁴ reported a case of meningitis in a laboratory technician who had been infected with meningococci while at work in the laboratory. The patient was given antimeningococcus serum intraspinally and intravenously. Subsequently the patient got well, and the spinal fluid sterile. This was followed by meningeal symptoms with sterile spinal fluid and a cell count of 4536. He concluded that the final symptoms and signs were due to aseptic meningitis caused by the serum.

There is still another possibility of developing so-called aseptic meningitis and that is as the result of lumbar puncture. Hurxthal⁵ recently

the corneal reflex is absent and anesthesia complete. By this time 5 to 10 cc of paraldehyde will have been given and some minor operations may be performed, but as the drug is rapidly excreted by the lungs usually the whole 15 cc will be required. The method is practically safe and it has been used in cases of grave cardiac and pulmonary disease with perfect success."

Atker⁴ the next year described a similar technique for the administration of paraldehyde in tetanus. In this case 15 cc each of paraldehyde and ether in 150 cc normal saline were given daily for eight days. The patient recovered.

Bastedo¹ mentions the intravenous use of 2 per cent paraldehyde in normal saline as a general anesthetic for short operations. He remarks that "anesthesia ceases when the infusion is stopped but sleep lasts for several hours" and none of the other half dozen standard texts in pharmacology which were consulted could reference be found to the parenteral administration of paraldehyde. Examination of the *Index Medicus* and the *Quarterly Cumulative Index* for the past ten years failed to reveal any references to the parenteral use of paraldehyde for the control of pain and convulsive states. Though no claim of originality is made it seems worth while to report the following observations because of the usefulness of this drug in properly selected cases especially where morphine has proved ineffective.

My first experience with intramuscular paraldehyde was in the case of a patient who had become maniacal after a hemorrhaphy. Morphine in the usual hypnotic doses was ineffective and physical restraint was deemed unwise because of the operative wound. Eight cc of paraldehyde were injected deep into the buttock as rapidly as possible. The patient lost consciousness before the syringe had been emptied and a peaceful sleep of some six hours followed. Equally good results were obtained in two other cases who had become unmanageable. A case of acute alcoholism who had become maniacal was subdued by this method so that gastric lavage could be carried out.

Encouraged by these results the drug was next tried in the terminal convulsive stages of cerebral hypertension which could no longer be controlled with morphine. Complete relaxation was obtained at once and the patient fell into a quiet sleep for several hours. This procedure had to be repeated a few days later but each time the convulsions were satisfactorily controlled. By this method it has been possible to control the convulsions of several other cases of advanced vascular disease. Intramuscular paraldehyde has not to my knowledge been used in eclamptic convulsions but it would seem worth trying as its action is rapid and safe.

Because of its rapidity of action it was given to relieve the pain of a coronary thrombosis

in which large doses of morphine had failed to control. This patient lost consciousness before the needle was withdrawn from the buttock and a quiet sleep lasted for several hours. The cardiac pain on awakening was negligible in this case. This procedure has been used in five other instances of coronary thrombosis where morphine had failed to bring relief. Equally good results were obtained though the loss of consciousness did not result so quickly in all these cases as in the first one. However, the patients admitted relief of pain within two minutes of administration and were asleep within five minutes. So striking is the result with 8 to 10 cc of paraldehyde that one almost hesitates to subject the patient to the extra twenty minutes of suffering while waiting to see if the morphine will be adequate.

There is one serious drawback to intramuscular paraldehyde in addition to the unpleasant odor imparted to the breath. It is highly irritating and its injection is accompanied by severe burning pain. If enough is given to produce immediate unconsciousness, however, very little suffering is caused though some soreness persists. When paraldehyde is injected intramuscularly the undiluted USP drug is used. Eight cc may be considered an average dose for an adult weighing about 140 lbs. I have frequently given 10 and occasionally 12 cc to very large or obstreperous patients. The objection to these larger doses lies not in their toxicity but in the discomfort and difficulty encountered in injecting such a large amount of fluid into the muscles especially when that fluid is as irritating as paraldehyde. Even with these larger doses however I have found no evidence of necrosis. In fact the soreness at the site of injection is surprisingly transient considering the comments occasioned by the injection.¹ The patients who received this for the relief of pain all volunteered the statement that the respite from suffering more than compensated for the transient pain of injection. This procedure has been employed on more than twenty occasions without any evidence of necrosis. The injection, however, should be given deeply into the gluteus medius to avoid sloughing.

In the hope of avoiding the pain of intramuscular injection the intravenous route has been employed in a few cases. A patient⁵ suffering terrific pain from a coronary thrombosis was given 5 cc of undiluted paraldehyde into the vein at the rate of about 1 cc in three seconds. The patient lost consciousness in about ten seconds. Coincident with the onset of anesthesia was a slight amount of pharyngeal irritation accompanied by coughing and a strong smell of paraldehyde on the breath. After a few coughs the patient appeared completely relaxed and slept quietly for about an hour. Upon awakening the pain was much less severe and

could be adequately controlled with morphine.

Intravenous paraldehyde in 7 to 10 cc doses has also been used to control the restlessness and headache of a hypertensive patient with evidence of extensive cerebro-vascular pathology. This patient⁶ was violently nauseated by morphine and was unable to retain the barbituric acid derivatives by mouth or rectum. Quiet sleep was induced on each of six successive nights by the intravenous administration of 7 cc of paraldehyde. The sleep so induced would last several hours but could be greatly prolonged by the rectal injection of sodium amytal Gr. V-X which was retained if given after consciousness had been lost. It is interesting to note that this patient began to show some degree of tolerance to paraldehyde after two or three injections, as there developed a latent period of ten to fifteen minutes between the injection and the onset of deep sleep. Such cases are probably not proper subjects for this treatment as their pain is hardly severe enough to warrant anesthesia and the relief from minor symptoms is too transient to be of much help in the long run. In this particular case intravenous paraldehyde was used because we had apparently exhausted every other method of giving the patient quiet sleep. When this type of patient reaches the convulsive stage, however, parenteral paraldehyde is the treatment of choice as its action is swift and an anesthetic dose is

well within the limits of safety. Here it is often superior to morphine, for many of these patients have developed a degree of tolerance which makes difficult the estimation of a dose which will be immediately effective yet safe.

Tolerance to paraldehyde unquestionably develops and habit formation has been reported, but these should not be problems if the drug is used only occasionally to control severe pain or convulsive states requiring rapid anesthesia.

It must be admitted that paraldehyde, however administered, is unpleasant and for that reason it is not the first choice for the relief of pain. But it is cheap, stable, easy to procure, requires no sterilizing and has a wide margin of safety while being almost instantaneous in action when administered parenterally. This makes it an exceedingly useful drug for the control of convulsive states and for the relief of pain which is unaffected by morphine.

FOREIGN PROTEIN SENSITIZATION WITH MENINGEAL INVOLVEMENT DUE TO THE USE OF VACCINE*

BY WILLIAM E. HALL, M.D.,† AND THOMAS P. MURDOCK, M.D.‡

FOREIGN protein sensitization with involvement of the meninges has not been dealt with extensively in American literature. The clinical picture is alarming. We feel that the disease occurs more frequently than has been believed and because of this the importance of the condition should be stressed.

Swift and Boots¹ go so far as to say that most patients receiving considerable amounts of therapeutic serum, develop serum disease. If this is so and certainly there seems to be sufficient evidence to support it, the condition warrants more than passing notice. The present tendency toward subcutaneous intramuscular, and intravenous injections of foreign proteins will in all probability increase the frequency of protein sensitivity, and also the more serious meningeal complications. Serum disease seems much more likely to follow the use of scarlet fever antistreptococcus serum, than any of the other serums.

In 1926 Kennedy² reported severe symptoms referable to the central nervous system in three patients with angioneurotic edema, which he attributed to a focal edema of the brain. In 1928³ he also reported several cases of involvement of the nervous system, and one case showing meningeal signs and symptoms following administration of serum. He suggested two possibilities as causative factors. The toxicity of the serum, or the urticarial edema of the perineural tissue.

Sheppe⁴ reported a case of meningitis in a laboratory technician who had been infected with meningococci while at work in the laboratory. The patient was given antimeningococcus serum intraspinally and intravenously. Subsequently the patient got well, and the spinal fluid sterile. This was followed by meningeal symptoms with sterile spinal fluid and a cell count of 4536. He concluded that the final symptoms and signs were due to aseptic meningitis caused by the serum.

There is still another possibility of developing so-called aseptic meningitis and that is as the result of lumbar puncture. Hurxthal⁵ recently

called this to the attention of the profession. He mentioned the increased frequency of lumbar puncture as a diagnostic procedure, and also the increased frequency of its use in spinal anesthesia. He believes that because of these, the possibilities of developing this disease are definitely increased.

Goldman⁶ was stimulated to investigate aseptic meningitis because of the frequency with which the condition was found at autopsy. He showed that the condition occurred with great regularity in experimental animals that had received intraspinal injections of serum. Of course the question may here arise as to whether the condition is due in these cases to trauma to the meninges, or to the administration of serum.

Wilson and Hadden⁷ have recently written on the question of neuritis and multiple neuritis following serum therapy. They reviewed the literature extensively and reported several cases.

The accepted procedure in patients with suspected meningococcic meningitis has been to administer serum intraspinally and intravenously following the withdrawal of spinal fluid. In the light of the present case, we feel that this should be done only very cautiously, and only after a definite diagnosis has been made. In other words, we feel that serum should be administered intraspinally and intravenously, only in those cases in which the diagnosis is clear. In doubtful cases, the fluid should first be examined and if found positive, the serum is injected.

A thorough search of the available literature does not reveal a case of foreign protein sensitization with meningeal involvement, due to the use of a vaccine. That it does occur seems a certainty. The probability is that the sensitization is due to the foreign protein in the bodies of the bacteria. We feel that the use of vaccines in medicine has been increased to such an extent that the danger should be called to the attention of the profession. It is quite probable that many physicians, for one cause or another, frequently inject vaccines.

The accepted uses of vaccines for atrophic arthritis and pertussis, the uses of autogenous vaccines for various conditions, and the unscientific use of various kinds of stock vaccines for almost every infectious condition, mean that almost certainly there will be an increasing number of cases of foreign protein sensitization, and with these a certain number of cases with meningeal involvement.

All of the cases (except that reported below) that we have found in the literature and have reviewed, were associated with the use of serum, and most of the cases with the use of serum intraspinally whereas the case reported here was not associated with either.

We believe that the danger of developing serum disease is increased in children who have had diphtheria toxin-antitoxin, and because of

this, the danger of serum therapy is markedly increased. The use of toxoid in the future will, in all probability, lessen the number of cases of serum disease.

The condition is difficult to diagnose, particularly if the skin manifestations are not prominent. The difficulties are increased if, as is frequently the case, the patient is not clear mentally, and it is impossible to obtain a clear history. Given semi-consciousness, headache, opisthotonos, fever, vomiting, positive Kernig, and discrete spots on the skin, one most naturally assumes that the condition is meningitis, and the probable clinical diagnosis is epidemic cerebrospinal meningitis. The spinal fluid is under increased pressure and is turbid. (The injection of serum at that point adds insult to injury.) We feel that if there is any doubt as to the diagnosis, treatment should be postponed until the spinal fluid has been examined.

We think there are two points worthy of mention as to differential diagnosis. First, the patients do not look so ill as the findings or signs would indicate, secondly, the low leucocyte count is not in conformity with the clinical picture of epidemic meningitis. It is now generally accepted that at the onset of symptoms due to foreign protein sensitization, there is leukopenia. Later on it is common to find a leukocytosis. We have the feeling that many cases of meningeal involvement due to foreign protein sensitization have gone unrecognized because of the acceptance of the syndrome as generally outlined, that is, prostration, fever, adenopathy, urticaria, painful joints, and vomiting following the administration of a foreign protein by injection. Meningeal involvement not being sought for or expected, is overlooked.

CASE REPORT

- H K a white female patient aged 43 years was admitted to the Hospital on April 3, 1933.
- C C Headache and vomiting.
- P H The past history disclosed the usual children's diseases without complications. Late in 1931 she had an attack of furunculosis lasting several weeks. In 1932 she was ill with "rheumatism" for several weeks. She had recurrence of this for a few weeks prior to admission to the hospital. There was no past history of hay fever or previous urticaria.
- F H Mother living and well. Father dead cause unknown. One sister living and well. One brother has sinus trouble.
- P I The onset of the present illness occurred suddenly on the day before admission with headache, vomiting and backache. These symptoms persisted all day when one of us (W. E. H.) was called to see her. A clear history was impossible because the patient was semiconscious. The temperature was 102° pulse 100 respirations 30.
- P E Pupils equal and react to light and accommodation. Conjunctivae and sclerae injected. Moderate edema of both eyelids. No extraocular palsies. Tongue moist. Teeth in good con-

dition. Pharynx clear Neck stiff No tenderness over sinuses No facial palsies Thyroid not enlarged Cervical glands not enlarged Lungs negative Heart not enlarged, sounds of fair quality, systolic murmur over the mitral area. Pulmonic second sound was booming and greater than the aortic second sound Bl Pr 145/85 Liver and spleen could not be felt There were no tender points and no masses There was an old scar in the right lower quadrant. Pelvic and rectal examinations were negative There were prominent veins in the left leg The right knee jerk was hyperactive Babinski negative On her back chest, abdomen and over the backs of her hands and wrists were sharply defined red spots varying in size from one centimeter to three centimeters in diameter These were surrounded by a narrow ridge of grey and faded on pressure

A diagnosis of meningitis was made and she was admitted to the Meriden Hospital A lumbar puncture was done The fluid was slightly cloudy and under increased pressure She was given antimeningococcal serum intraspinally Examination of the spinal fluid showed the total cell count to be 6804 polymorphonuclears 89 per cent, small lymphocytes 6 per cent, large lymphocytes 5 per cent. No organisms were found on smear or culture Globulin 4 plus No reduction of sugar Colloidal gold curve 1244445533 (meningitic curve) Wassermann negative

Following this the patient improved rapidly On the fourth she still complained of some headache but this was not so severe The temperature on the evening of April 4 1933 was 99.8° rectally pulse 100 respirations 20 From then on until discharge the vital signs were in normal range

On April 4 1933 it was possible to obtain a clear history from the patient. She stated that she had been taking some injections for 'rheumatism' The doctor informed us that she had been given several injections of antistreptococcal vaccine for her arthritis the last injection was 1 cc and had been given on the day preceding the onset of her present illness We also learned that she had an attack of urticaria following vaccine injection one month ago

On April 4 1933 lumbar puncture was repeated. The total cell count was 4740 polymorphonuclears 88 per cent. No organisms were found on smear or culture

The urticaria had practically disappeared on April 5 1933 two days following admission

On April 5 1933 lumbar puncture was repeated. The cell count was 1620, and polymorphonuclears 86 per cent.

The laboratory findings were RBC 4040000 WBC 6000 Hemoglobin (Tallqvists) 80 per cent, polymorphonuclears 71 per cent small lymphocytes 19 per cent large lymphocytes 10 per cent filamented 84 per cent, nonfilamented 16 per cent. Blood Wassermann negative Non protein nitrogen 40 mgs Blood sugar 136 mgs Blood culture negative

The patient continued to improve and was discharged on April 10 1933 one week after admission Two days later on April 12 1933 the patient complained of feeling weak, of smarting of the eyes and of vague pains On the next day April

13 1933, she was readmitted to the hospital On admission the temperature was 99°, pulse 100, and respirations 20

There were a few urticarial spots on her back and chest and slight edema of her eyelids, otherwise the findings were essentially the same as on the previous admission A spinal tap was done, and the total cell count was 564 with 77 per cent polymorphonuclears The fluid was under increased pressure and was slightly turbid On April 15, 1933 the rash involved her arms forearms, legs, chest and back and itched furiously A dermatological consultation was requested, and Dr R V Quinnlan saw her and concurred in the diagnosis His tamine phosphate was used at this time for the urticaria This was followed by local relief. On April 17 1933 the rash was still present, but not so marked and she developed some painful, red and swollen joints involving her wrists and great toes This gradually subsided and from then on her convalescence was uneventful A lumbar puncture was done on April 21 1933 and showed a cell count of 166, with polymorphonuclears 56 per cent, and lymphocytes 44 per cent Smear and culture were negative The patient was discharged on April 25, 1933

It is our feeling that the recurrence in this patient was due to the administration of anti-meningococcal serum before the serological work had been completed and the diagnosis established

That the original attack was caused by streptococcal vaccine seems certain This opinion is supported by the fact that a history was obtained of a previous attack of urticaria one month before the present attack, and that it followed an injection of streptococcal vaccine

Of particular interest is the extremely high cell count, ranging from 6804 to 4740, to 1620, to 564, and finally to 166

CONCLUSIONS

- 1 The literature on meningeal involvement due to foreign protein sensitization has been reviewed
- 2 The disease can be caused by vaccines
- 3 This warning is issued because of the increased frequency of the use of serums and vaccines

RECURRENT DISLOCATION OF THE SHOULDER

BY FREDERIC JAY COTTON, M D,† AND GORDON MACKAY MORRISON, M D ‡

RECURRENT anterior (subcoracoid) dislocation of the shoulder is a not unusual sequel of reduced traumatic dislocation. It occurs in young strong active men, usually, and urgently calls for relief. A large number of operations for cure have been devised, not a few of which have excellent records as to end results—so far as checking relaxation is concerned*.

This note is a plea for a really *restorative, reconstructive* operation that sacrifices no structure, no function, and really reproduces original function and power. It seems to be at least as effective as any other, when performed as outlined.

The essential or at least constant lesions found† are the general slack of the whole capsule, particularly in front toward the axilla, and, associated with this, a retraction of the subscapularis muscle.

It is futile to talk of anything that has to do with the *tendon* of the subscapularis.

There is no such thing. That is to say, no isolated tendon structures, differentiated from the capsule into which the muscle is inserted.

The *muscle* is inserted on the front face of the thick fibrous capsule, normally within an inch of the glenoid edge, in these cases of recurrent luxation it may be found retracted not less than two and one-half inches toward the midline, to be found only by deep retraction, sometimes only after strong dragging outward with heavy double hooks on the V-shaped portion of the fibrous capsule, cut and loosened for advancement. (See figure, A, 8.)

Oddly enough, the muscle once found is normal looking, not evidently atrophic.

The essence of the operation here described is an advancement of the muscle to its normal relation to the joint, combined with a reefing of the loose capsule in front and below.

The operation began as an anterior capsulorrhaphy devised and shown by the late Dr Herbert Leshe Burrell.

Thus alone proved not reliably efficient, and there have been added a reefing upward and forward of the loose capsule in the axilla,—and, more particularly, a really anatomical dissection of that part of the capsule into which the subscapularis muscle should be inserted, and an advancement of this muscle, often through one and one-half inches to its proper anatomical

place. So modified, the operation works. The approach is by the familiar Hueter incision, from an inch above the coracoid process down along the inner edge of the deltoid to an inch below the insertion of the great pectoral.

The deep approach is between the deltoid and

the clavicular portion of the pectoral. In this interval lies the cephalic vein, which may be retracted inward with the pectoral. It is often convenient to cut the upper half of the tendon of the pectoralis major. This gives much more room, and does no harm. After the great muscles are once separated, one comes directly onto the capsule. Rotate the arm outward and the head presents. Further procedure may best be understood from the drawings. The flap that is to include the subscapularis muscle goes through

*Turner Thomas Clairmont Kellogg Speed Oudard Hendersen Nicola Roberts et al

†We have almost never—only once to be exact—found even a trace of glenoid defect though no doubt it does occur.

‡Cotton and Morrison—For records and addresses of authors see page 817 Issue of April 12 1934

the fibrous capsule to the synovial capsule, which is at this place, a separate layer

The whole operation can be done without opening the joint. Any opening that may be made into joint or bursa is of no consequence whatever. We have never taken out any part of the undoubtedly redundant synovial layer, nor have I seen reason to do so. Suturing of the shortened V-shaped flap carrying the muscle, to the cut edge of capsule near the biceps groove must be very solid, it must withstand some strain. Chromic gut No 2 is good. There is no room to use fascia. The V brought up from underneath out of the axilla is trimmed and used as a covering flap. It is under no tension—suturing with No 1 chromic gut is ample.

The mechanical part of the operation done, the wound closes itself. To control undue dilatation of the stripped cephalic vein one may bury it between the great muscles and lightly suture them about it. The cut pectoral insertion needs no sutures. The arm is put up with elbow at side, and the forearm across at the waist. Pressure dressing is not feasible. A light soft sand-bag over the front of the shoulder for from 12 to 24 hours is advantageous, and usually well tolerated.

Motion begins at three weeks, and useful motion with solid healing follows within ten weeks at most. There is always, if the operation is properly and solidly done, some limitation of abduction and outward rotation for from four to six months*.

CASE 1 R W M male aged 27 In Public Health Service. Seen March 21 1920. Dislocated left shoulder at bayonet practice in September 1917 and a week or so later from a slight backward fall. Discharged from the army December 1917. While at home the shoulder was out four or five times. Redrafted September, 1918. Discharged again in May 1919 for same disability. Shoulder (left) has been dislocated seventeen times in all despite an operation at the Boston City Hospital in 1918 and two operations in the army. Six weeks ago the right shoulder went out while the doctor was reducing the left shoulder. The right has been out three times in all. General musculature poor about both shoulders and *scapulae* very poor. A neurologist fails to confirm the suspicion of progressive muscular atrophy. The left shoulder is a mess of scars front and back. Admitted to the Parker Hill Hospital April 12 1920. Operated on the left shoulder April 16 1920 (F J C). Usual anterior incision. Typical Burrell-Cotton operation with capsule reefing and advancement of subscapular muscle. All musculature is poor.

Operated elsewhere on the right side twice in 1921 with recurrence.

Examination March 24 1922. Left shoulder shows muscle redeveloped practically normal. Right shoulder has limited motion and two scars. Subluxation rather than total dislocation. Operated at City Hospital 1922 (F J C) for right shoulder.

Advantageous to clear this last hindrance is the free pendulum exercise by the patient who lies on a bed face down, with the arm hanging over the edge and a bit later the swinging of light Indian clubs.

Excision of scar, type Burrell-Cotton operation right shoulder. Seen July, 1933. Not very good musculature about shoulders even now, and some limitation of motion on right. There has been relaxation of either shoulder after the muscle capsule reefing.

CASE 2 V R female, aged 24. Seen September 1929. Hospital technician. She was thrown from a 'cutter' eight years ago, and dislocated her shoulder. Luxation since then five times needing reduction five other times partially dislocated. Joint has an unsafe feeling and is sometimes painful. Operation recommended. Finally came to operation June 29, 1930 at the Boston City Hospital (F J C). Type Burrell-Cotton operation. Normal recovery. Examined June 1933. Shoulder in normal shape in all ways. Has had no recurrence.

CASE 3 E F C, male aged 23. Wireman in electric corporation. Seen October 19, 1932, referred by the late Dr John F Sweet of Newport, Rhode Island.

On October 17 1931 he reported that he injured his left shoulder cranking a truck about five years ago (dates are vague) and it has 'gone out' twelve times a year since then. The last time, a few days ago Dr Sweet had to put it back, and send him to Boston.

He proved to be a young Frenchman of admirable build and amazing muscle. The shoulder showed nothing but was a little sore.

Operation at the Faulkner Hospital October 1932 (Cotton and Morrison). Usual incision; approach. Marked looseness of capsule, in fact only Subscapularis much retracted. Usual excision and reefing done—taking up muscle and capsule slack of near two inches. Six double No 2 chromic gut sutures to hold it, in view of enormous muscles. Sutures through muscles control dilatation of huge cephalic vein. No reefing of axillary part of capsule.

Motion begun early and from December 15th he was allowed full and free use of it.

He was last seen August 25, 1933. He has been using the arm continuously but only within a few nights has he had absolutely full upward motion. Now 100 per cent motion and use. The deltoid muscle is nearly as huge as on the right. No sign of recurrence. In a young giant like this it pays to quilt the capsule liberally and solidly, but there for a time for this very reason some resulting limitation of motion.

CASE 4 H G male. Original injury two years before. Out several times most recently while swimming. He demands relief. Admitted September 11 1928. Discharged September 22 1928. Reoperation September 13 1928 at the Boston City Hospital.

Usual aseptic precautions. Anterolateral incision over left shoulder. Cephalic vein located. The deltoid was separated from the pectoralis major and retracted with the cephalic vein. The shoulder capsule was exposed, a reef taken in the capsule and the subscapular tendon shortened over the capsule. No recurrence to date. Examination July 1933.

CASE 5 G McL aged 22 florist, seen May 1933 referred by Dr Robert J Graves of Concord, N H. No history of original trauma but for several years about once a year the right shoulder has been throwing out. Ten days ago Graves had to reduce it. Examination showed a vigorous young man with only local difficulty. Operation June 2 1933 at the Faulkner Hospital. Typical incision and technique. The subscapularis was advanced about an inch and a half and secured.

with No 2 chromic gut. The lower capsule in the axilla was not lax, but caught up in a V, very snugly, according to the usual technic

Motion from June 26, 1933 On July 6, 1933, set about vigorous limbering up exercises A prognosis of six months before regaining absolutely normal abduction and outward rotation was given Discharged July 6, 1933 No recurrence as yet

CASE 6 M K, female, aged 35 Seen March 17, 1927 Au industrial case, completely disabled from recurring subcoracoid dislocation of the shoulder, often "out" with frequent subluxations in the intervals

Operated on April 13, 1927 at the Faulkner Hospital with Dr Henry Marble Usual approach The capsule proved unusually "baggy" in the axilla The

subscapular muscle was broad, flat, soft, displaced inward and downward, but easily drawn into the wound The usual operation was varied by using a large inverted V cut in the capsule, enabling a shortening and raising of the subscapularis to be combined with an unusual pulling up of the capsule from below The V flap was liberally trimmed, brought up in front and sutured as usual

Healing was prompt, but limbering up of the joint went very slowly, perhaps partly because she lived 30 miles from Boston.

There was long persistent muscle spasm, and obviously a neurotic element in the case, with varying disability

Up to November 3 1928 however there had been no recurrence of luxation or subluxation

MEDICAL PROGRESS

PROGRESS IN THE DIAGNOSIS AND TREATMENT OF SYPHILIS, 1933

BY AUSTIN W CHEEVER, M D *

THERE have been a few years that were epochal in the history of the treatment of syphilis 1905, with the discovery of the spirochete, 1906 with the development of the Wassermann reaction as a practical test for syphilis, 1910, with the success of Ehrlich's six hundred and sixth experiment, and a few others With these exceptions, the progress in any one year has not seemed consequential, but our small advances have been cumulative and over a period of years they show a long step forward as C Morton Smith¹ makes clear in his review of the changes in the treatment of syphilis during the last twenty years He traces our gain in the relief and control of this disease and in our efforts to educate the public in its attitude toward the syphilitic One proof of our success in the latter respect is evidenced by the fact that the past year in Boston saw what an officer of the Massachusetts Society for Social Hygiene² hailed as "the most recent single event of importance in the field of social hygiene" It was the production of the picture "Damaged Lives" which played to crowded houses Equally gratifying was the fact that Boston dramatic critics dared to refer to the keynote of the play, gonorrhea and syphilis, by name without resorting to euphemisms In this same city Nelson of the State Department of Public Health³ has been giving radio broadcasts on syphilis and gonorrhea with, it is said, not a single complaint against their frankness but a number of favorable comments and requests for further information At least one newspaper printed an editorial commending the talks

However, there still remains much educational work to be done when a court⁴ will annul a marriage because a woman having had ad-

vanced syphilis before marriage did not disclose the information to her husband With the same lack of understanding the appellate court, Louisiana,⁵ has ruled that an insurance policy which excludes from its coverage venereal diseases imposes no obligation on the insurer to compensate for the effects of syphilis, even though innocently acquired

If we are to prevent blindness from interstitial keratitis and the mental and physical defects of congenital syphilis, the medical public must be educated to greater vigilance in the care of the pregnant mother Lees⁶ reports that in Edinburgh among 1000 untreated pregnancies only 24.5 per cent of the children were sufficiently healthy to survive while a similar survey of efficiently treated mothers showed 89.2 per cent of healthy children, and an even larger percentage, if the treatment of the mother was begun before the sixth month of pregnancy At the Memphis General Hospital⁷ 1000 cases of syphilis in pregnant women were discovered over a period of ten years Of those receiving treatment 65 per cent had normal, full-term babies with no evidence of syphilis Of those receiving no treatment none had a normal, full-term infant with no serological or clinical evidence In view of these reports it is encouraging to know that the American Medical Association at its annual meeting in 1933 adopted a resolution⁸ requesting the House of Delegates to appoint a committee to arrange methods by which cooperation might be secured with the American Medical Association, the National Society for Prevention of Blindness, the American Social Hygiene Association, the obstetric and ophthalmologic societies, the American Dermatological Association, and public health organizations and such others as can help, to see that blood examinations are made of all pregnant women so that all cases of syphilis may be treated

The use of artificially produced heat in the treatment of central nervous system syphilis and the favorable results from malaria have stimulated many investigators to try to devise less dangerous and more controllable methods of producing fever. M. O. Nelson⁹ recommends combined typhoid vaccine which he found brought improvement in patients with resistant neurosyphilis. Epstein and Paul¹⁰ for two years have been using a diathermy apparatus capable of raising the body temperature to 41.1° (106° F). They describe their technique and results on a group of twenty-eight patients with various forms of central nervous system syphilis. Clinical improvement was noted in patients with all types of the disease but especially so in those with tabes dorsalis. One fatality occurred in a patient of advanced age with marked mental deterioration. Graham¹¹ obtained results better than those from malaria, he thinks, in twenty-four cases treated by diathermy though he records one death due to respiratory failure attributable to treatment. Worthing¹² describes a diathermy machine in which so far only a small number of patients have been treated. His results agree in general with those of other workers, but the author emphasizes the extreme discomfort of the patient after the temperature rises above 102 degrees.

Freeman, Fong, and Rosenberg¹³, on the other hand, found the substitution of diathermy for malaria in the treatment of dementia paralytica far from promising. They feel that early reports on the use of mechanical measures for producing fever have been premature. O'Leary¹⁴ too feels that the results from malaria are still superior to those obtained from electrical machines. He has observed over a period of eight years almost one thousand patients with neurosyphilis who were treated with malaria and he has found that in more than three-fourths of the cases of asymptomatic dementia paralytica, clinical progress of the disease was arrested, and the serologic tests of the spinal fluid became reversed to complete negativity in almost half the cases of asymptomatic neurosyphilis in which routine measures of treatment had previously failed to influence the serology. The results in the treatment of tabes dorsalis and of the tabetic form of dementia paralytica were likewise encouraging.

In 1932 Gennerich¹⁵ reported on a new mercury preparation which he found intensely effective for all stages of syphilis but less active than arsphenamine. This year Lawless¹⁶ reports on this drug colloidal mercuric sulphide. He found it painless with no palpable infiltration and decidedly effective though too slow to be of use in the infectious stages of syphilis. It is highly recommended as a supportive drug with the arsphenamines and bismuth. A serious drawback is its rather constant resistant staining of the skin at the site of injection.

Because of inconclusive clinical results with 50 per cent mild mercurous chloride injections, Cole et al.¹⁷ made a study of the mercury excretions in order to obtain a better criterion of its true absorption from the skin. They found it very poorly absorbed.

After a study of the different types of bismuth preparations watery solutions, a solution in ethylene glycol, oily solutions and oil suspensions, Sollmann, Cole, and Henderson¹⁸ decided that the total dosage is much more important than the particular preparation used. They were impressed by the similarity in the absorption and excretion rate of all these compounds except the oil suspension of bismuth salicylate which showed much slower absorption and excretion. Distinct doubt is thrown upon the desirability of too rapid absorption in bismuth because of a correspondingly rapid excretion rate and the accompanying tendency to overburden the kidneys and liver. After studying five typical bismuth preparations as to rate of absorption distribution in kidneys and liver, urinary excretion, irritation at site of injection, and toxicity Thompson et al.¹⁹ show that it is not yet established that a rapid absorption rate will result in a more effective concentration against syphilis. They confirmed the intimate relationship between absorption rate and toxicity, the preparations showing fastest absorption being most toxic.

An excellent summary of our knowledge of bismuth at the present time is found in a discussion of bismuth compounds by Irgang, Alexander and Sala²⁰.

Bismuth has been recommended as a prophylactic against syphilis and in this connection it is interesting to see the report by Zetterholm²¹ of a reinfection in a patient during the course of continuous bismuth treatment. The same situation holds for stovarsol by mouth which has been recommended as a prophylactic. Tzanck et al.²² report an instance of a patient's developing syphilis while taking stovarsol by mouth for non-syphilitic lesions.

After studying the effects of arsphenamine and tryparsamide in systemic syphilis and neurosyphilis in sodoku and in malaria Solomon, Epstein and Berk²³ conclude that the value of the former drug is in its spirocheticidal and plasmodicidal effect as indicated by its action in stopping fever in malaria and in clearing the blood of plasmodia in inoculation malaria, while tryparsamide showed no effect on either fever or blood. However, this latter drug shows a power to stimulate tissue to rapid repair, a local action within the local areas of the nervous system.

Raziss and Severac²⁴ made a very careful comparison of bismarsen and arsphenamine in rabbit syphilis. They conclude that bismarsen is as effective as arsphenamine in experimental syphilis in rabbits.

with No 2 chromic gut. The lower capsule in the axilla was not lax, but caught up in a V, very snugly, according to the usual technic.

Motion from June 26, 1933 On July 6, 1933, set about vigorous limbering up exercises A prognosis of six months before regaining absolutely normal abduction and outward rotation was given Discharged July 6, 1933 No recurrence as yet

CASE 6 M K., female, aged 35 Seen March 17, 1927 An industrial case, completely disabled from recurring subcoracoid dislocation of the shoulder, often "out" with frequent subluxations in the intervals

Operated on April 13, 1927 at the Faulkner Hospital with Dr Henry Marble Usual approach The capsule proved unusually "baggy" in the axilla. The

subscapular muscle was broad, flat, soft, displaced inward and downward, but easily drawn into the wound The usual operation was varied by using a large inverted V cut in the capsule, enabling a shortening and raising of the subscapularis to be combined with an unusual pulling up of the capsule from below The V flap was liberally trimmed, brought up in front and sutured as usual

Healing was prompt, but limbering up of the joint went very slowly, perhaps partly because she lived 30 miles from Boston

There was long persistent muscle spasm and obviously a neurotic element in the case, with varying disability

Up to November 3, 1928, however, there had been no recurrence of luxation or subluxation
